Adaptive immune responses have a degree of flexibility that is unparalleled in molecular recognitions systems. This flexibility has a dangerous side that is constrained by anatomy and strong coupling to innate immunity. Autoimmune disease may result when weak points in tolerance mechanisms intersect with infection or tissue damage, leading the adaptive system to attack its own organs in a self-amplifying process of tissue destruction, inflammation, and inappropriate anatomic adaptation such as tertiary lymphoid tissue genesis. These processes are highly relevant to rheumatoid diseases. For example, a mouse model for autoimmune rheumatic disease called the *KRN transgenic mouse* develops a T cell– and B cell–dependent joint disease.[104] Similarly, mutations in the T cell signaling protein ZAP-70 lead to failure of tolerance mechanisms in the SKG mouse, which recognizes autoantigens that are shared with human rheumatoid arthritis.[106] Strategies to break these cycles by attacking innate or adaptive immune system components nonspecifically have met with success, but more specific strategies may reduce negative consequences of general immunosuppression.[107]

CHAPTER 19

# Autoimmunity

Dwight H. Kono • Argyrios N. Theofilopoulos

**KEY POINTS**

- Autoimmunity ranges from physiologic levels of autoreactivity to overt autoimmune disease, in part reflecting the complexity of the immune system, the presence of multiple layers of tolerance mechanisms, and genetic heterogeneity.
- Autoimmune diseases can be classified by the extent of organ involvement (organ-specific to systemic), innate immune system requirements, and effector mechanisms. However, each type of autoimmune disease has unique pathophysiologic characteristics.
- Advances in defining the mechanisms underlying autoimmune diseases have been greatly facilitated by delineation of the innate and adaptive immune systems.
- Autoimmune disease susceptibility is multifactorial, involving genetic, environmental, sex, and other factors, with genetic predisposition usually playing a central role. The contributions of these factors are typically heterogeneous, partial, and additive.
- Animal models have been critical for understanding the pathophysiology of autoimmune diseases and provide fundamental insights into genetic, mechanistic, and pathologic processes. Spontaneous animal models do not exist for most autoimmune diseases.
- Progress in delineating pathways has revealed many key genes and molecules in autoimmune diseases that are of potential therapeutic relevance.

Autoimmune diseases represent a significant health burden for 3% to 9% of the general population, and rheumatology, perhaps more than any medical subspecialty, encompasses a broad array of such diseases that affect a wide range of organ systems (Table 19-1).[1-3] Consequently, rheumatologists have a great interest in defining the causes and pathophysiology of autoimmunity and in applying this information in the clinic.

The immune system must effectively defend against a diverse universe of pathogens while simultaneously maintaining tolerance to self-antigens. Recent advances have begun to clarify how this equilibrium is established and sustained and, importantly, have identified many critical factors and processes involved in the pathogenesis of autoimmune diseases. This chapter provides a general overview of autoimmunity, covering the definition of the term, general tolerance mechanisms for T and B lymphocytes, theories of how tolerance can be breached, and ways in which genetic and environmental factors have been implicated in breaking tolerance and producing disease. Emphasis is placed on manifestations and mechanisms related to rheumatologic pathoses.

## DEFINITION AND CLASSIFICATION OF PATHOGENIC AUTOIMMUNITY

Autoimmunity—that is, the immune response against self—evokes the specter of "horror autotoxicus," a term coined by Paul Ehrlich at the turn of the 20th century to depict the perceived disastrous consequences of this condition.[4] In fact, autoreactivity is more nuanced, ranging from a low "physiologic" level of self-reactivity essential for lymphocyte selection and maintenance of normal immune system homeostasis, to an intermediate level of autoimmunity that manifests as circulating autoantibodies and tissue infiltrates that are not associated with clinical consequences, to pathogenic autoimmunity associated with immune-mediated dysfunction or injury. From the clinical perspective, it is the transformation to pathogenic autoimmunity that demarcates significant from insignificant self-reactivity.

The diagnosis of an autoimmune disease is generally based on the presence of adaptive immune system–mediated disease caused by self-reactive antibodies, T cells, or both. For many common autoimmune diseases, more definitive evidence for an autoimmune cause has come from studies showing transfer of disease by autoantibodies or self-reactive T cells and from animal models exhibiting congruent characteristics. However, no universally accepted criteria exist, and some less well-characterized diseases that are currently considered to be autoimmune may turn out to have other causes.

An example of disorders that exhibit some characteristics of autoimmunity but are distinct in their pathogenesis are the autoinflammatory diseases.[5-8] These diseases are predominantly rare monogenic disorders typified by intermittent bouts of fever, rash, serositis, and arthritis caused by a widening spectrum of defects in the control of basic inflammatory pathways. Included in this category are familial Mediterranean fever, the cryopyrinopathies, hyperimmunoglobulinemia D with recurrent fever, familial cold urticaria, Blau syndrome, and others. These syndromes could be considered part of a broader definition of autoreactivity in which autoinflammatory diseases mediated entirely through the innate arm of the immune system comprise one end of the spectrum, while at the other end are autoimmune diseases that require both the innate and adaptive responses. Indeed, the possibility of a less stringent demarcation has been suggested by assessment of disorders such as Behçet's disease, systemic juvenile rheumatoid arthritis, and Crohn's

disease, which appear to manifest various degrees of both autoinflammatory and autoimmune features.

Autoimmune diseases can be classified as systemic or organ-specific depending on the extent of their clinicopathology (Table 19-2). The systemic category includes systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), scleroderma, primary Sjögren's syndrome, dermatomyositis, and systemic vasculitides. In systemic disease, autoimmunity targets ubiquitously expressed self-antigens, and end-organ injury is typically mediated by autoantibodies and, less commonly, T cells. In contrast, in organ-specific diseases, the self-antigens are typically cell- or tissue-specific in location or accessibility, and end-organ damage can be mediated by antibodies and/or T cells. Some of the more notable examples in this group, which span virtually all organ systems, include Hashimoto's thyroiditis, Graves' disease, multiple sclerosis (MS), type 1 diabetes mellitus (T1DM), anti-phospholipid (aPL) syndrome, pemphigus vulgaris, autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, and myasthenia gravis. It should be emphasized, however, that although the distinction of systemic and organ-specific disorders provides a conceptual framework, the individual pathophysiologies are more diverse than is implied by this simple classification. Autoimmune diseases are also classified by hypersensitivity reaction type based on the mechanism of adaptive immune system–mediated injury,[9] a topic that will be discussed later in the chapter.

## ANIMAL MODELS OF AUTOIMMUNITY

Much of what is known about the immune system and autoimmunity has been derived from studies in animals, particularly the mouse, which has an immune system and genome composition similar to that of humans. Many well-characterized autoimmune models exist in which investigators can manipulate genomes and immune systems, test interventions, and modify environments. Animal models of autoimmune disease can be divided into three main types based on their derivation: (1) spontaneous, (2) genetically modified, and (3) induced. Some of the more common or notable models are listed in Table 19-3.

Within the spontaneous group are models of SLE, RA, and T1DM. The lupus-prone strains commonly develop anti-DNA and immune complex–mediated kidney damage, but they also possess unique phenotypic characteristics and differ in the genes underpinning susceptibility.[10] The SKG arthritis model is a spontaneous, inflammatory, and erosive arthritis caused by a *ZAP70* mutation that, similar to RA, is associated with rheumatoid factor (RF) and antibodies to citrullinated proteins.[11] T1DM develops in nonobese diabetic (NOD) mice and biobreeding (BB) rats as a result of T cell–mediated destruction of β-islet cells.[12]

The genetically modified group, encompassing transgenic, site-directed genetic replacement (gene knockout or knockin) and *N*-ethyl *N*-nitrosourea (ENU)-mutagenized mice, is by far the largest, with more than 95 different models of lupus and many models of organ-specific diseases, particularly T1DM and MS.[10,12] The lupus models, primarily single gene knockout or transgenic mice, have provided a wealth of information related to immune tolerance and disease pathogenesis. Some examples are (1) confirmation of human SLE gene associations and elucidation of mechanisms, such as C1q and fragment, crystallizable γ receptor IIb (FcγRIIb) knockout mice; (2) discovery of novel mechanisms such as altered messenger RNA (mRNA) regulation in sanroque and miR-17-92 transgenic mice; and (3) identification of new pathways relevant to therapy, such as B cell–activating factor of the tumor necrosis factor family (BAFF) transgenic.

An example of an arthritis model created by genetic modification is the K/BxN mouse, a B6 × NOD hybrid expressing a transgenic T cell receptor, named KRN, that recognizes a bovine ribonuclease peptide on H-2K.[13] An acute severe inflammatory arthritis develops in these mice that is caused by antibodies to glucose-6-phosphate isomerase (GPI), an antigen that, although intra-cellularly and ubiquitously expressed, is mainly accessible to antibodies in joints.[14] Although GPI is not a major target in RA or other arthritides, the model has nevertheless been useful for investigating inflammatory mechanisms in arthritis.[15]

Other genetically modified models of spontaneous arthritis include the human T-lymphotropic virus (HTLV)-1 tax transgenic, the tumor necrosis factor (TNF) transgenic, the interleukin-1 receptor antagonist (IL-1ra) transgenic, the IL-1 transgenic, and a gain-of-function knockin mutant of CD130, the signaling component of receptors for several cytokines including IL-6, IL-11, IL-27, and leukemia inhibitory factor (LIF).[16] Several genetically modified models of T cell–mediated organ-specific disease have been developed that consist of T cell receptor (TCR) transgenic T cells that recognize tissue-specific antigens in organs such as the brain and pancreatic islets or employ a slightly modified version in which mice are double transgenic for both an antigen expressed in a tissue of interest and the corresponding TCR.[17-20] By allowing analysis of single autoreactive T cell clones, these models have yielded considerable insights into

**TABLE 19-2** Classification, Mechanisms, and Models of Autoimmune Diseases

| Syndrome | Autoantigen | Consequence | Hypersensitivity Type | Animal Model (Example) |
|---|---|---|---|---|
| **Systemic** | | | | |
| aPL syndrome | β2-GP1 (apoH) | Vascular thrombosis, recurrent miscarriages | II | (NZW × BXSB)F1 |
| Microscopic angiitis | p-ANCA (MPO) | Glomerulonephritis, leukocytoclastic vasculitis, mononeuritis multiplex, lung inflammation | III | anti-MPO |
| Granulomatosis with polyangiits | c-ANCA (PR3) | Vasculitis of kidney, upper airway, and lungs | III | None |
| Cryoglobulinemia | Unknown | Cutaneous vasculitis, glomerulonephritis | III | MRL-*Fas*$^{lpr}$ |
| SLE | Nucleic acids | Glomerulonephritis, skin lesions, arthritis, CNS lupus, and others | III | MRL-*Fas*$^{lpr}$, BWF1, BXSB, NZM2410 |
| Systemic sclerosis | Unknown | Fibrosis of multiple organs | III | Tsk/$^{+}$ mice, bleomycin-induced |
| RA [†] | RF IgG immune complexes, citrullinated proteins, other joint antigens | Arthritis and associated manifestations: rheumatoid nodules, rheumatoid lung, Felty's syndrome | III | CIA, PGIA, AA, SKG, K/BxN, BxD2, citrullinated-protein-immunized DR4-IE transgenic |
| **Organ-Specific** | | | | |
| Graves' disease | TSH receptor | Stimulation of receptor; hyperthyroidism | II | EAT |
| Myasthenia gravis | ACh receptor | Receptor blockade/modulation; neuromuscular paralysis | II | EAMG |
| Autoimmune hemolytic anemia | RBC surface antigen | C′ and FcγR-mediated cell destruction; anemia | II | NZB |
| Idiopathic thrombocytopenic purpura | Platelet integrin GpIIb:IIIa | Thrombocytopenia; purpura, bleeding | II | (NZW × BXSB)F1 |
| Goodpasture's syndrome | Type IV collagen* and other basement membrane antigens | Pulmonary hemorrhage, glomerulonephritis | II | Anti-CIV, anti-laminin |
| Pemphigus vulgaris | Epidermal cadherin (Dsg3) | Bullous skin lesions | II | anti-Dsg3 |
| Neonatal lupus | Ro/La | Cutaneous LE, heart block | II | Anti-Ro52[254] |
| T1DM | Pancreatic β-cell antigens | Pancreatic islet inflammation, diabetes | IV | NOD, BB |
| Multiple sclerosis | CNS antigens; MBP, PLP, MOG in animal models | Progressive CNS inflammation and paralysis | IV | EAE, Theiler's virus infection |

*Most likely hypersensitivity type.
[†]Both systemic and organ-specific.
AA, Adjuvant arthritis; ACh, acetylcholine; ANCA, anti-neutrophil cytoplasmic antibody; anti-CIV, anti–type IV collagen; anti-Dsg3, anti-desmoglein 3; aPL, anti-phospholipid antibody; apoH, apolipoprotein H; β2-GP1, β2-glycoprotein 1; c-ANCA, cytoplasmic anti-neutrophil cytoplasmic antibody; CIA, collagen-induced arthritis; CNS, central nervous system; EAE, experimental autoimmune encephalomyelitis; EAMG, experimental autoimmune myasthenia gravis; EAT, experimental autoimmune thyroiditis; Ig, immunoglobulin; LE, lupus erythematosus; MBP, myelin basic protein; MOG, myelin oligodendrocyte glycoprotein; MPO, myeloperoxidase; NOD, nonobese diabetic; p-ANCA, perinuclear anti-neutrophil cytoplasmic antibodies; PGIA, proteoglycan-induced arthritis; PLP, proteolipid protein; PR3, proteinase 3; RA, rheumatoid arthritis; RBC, red blood cell; RF, rheumatoid factor; SLE, systemic lupus erythematosus; T1DM, type 1 diabetes mellitus; TSH, thyroid-stimulating hormone. Other abbreviations are mouse strains.

tolerance mechanisms and disease pathophysiology. Similarly, autoreactive B cell receptor transgenics or knockin models have been developed that have been crucial for defining B cell tolerance mechanisms.[21-27]

The induced models encompass a wide variety of both systemic and organ-specific diseases. More commonly studied models of systemic disease include tetramethylpentadecane (TMPD; also called pristane)-induced autoimmunity, mercury-induced autoimmunity, and chronic graft-versus-host disease.[28-30] All models bear similarities to human SLE in producing anti-nuclear antibodies and immune complex deposits but differ in pathophysiology and strain susceptibility. For the induced models of organ-specific diseases, a common approach is to immunize rodents with a self-antigen or closely related peptide or foreign antigen, plus a strong adjuvant, usually complete Freund's. This approach makes it possible to induce autoimmunity in virtually all organ systems and to produce diseases mediated by cellular as well as humoral mechanisms. Some of the more commonly studied organ-specific models developed by this approach include collagen-induced arthritis (CIA), proteoglycan-induced arthritis (PGIA), and experimental autoimmune encephalomyelitis (EAE), but many others exist that are directed to the thyroid, eye, gonad, nerves,

**TABLE 19-3** Partial List of Autoimmune Disease Models

| Model | Autoimmune Disease | Species | Notable Characteristics |
|---|---|---|---|
| **Spontaneous Variant** | | | |
| MRL-Fas$^{lpr}$ | SLE | Mouse | Fas mutation, defective apoptosis, lymphoproliferation, human counterpart ALPS |
| (NZB × NZW)F1 | SLE | Mouse | Female predominance |
| NZB | SLE, AIHA | Mouse | Anti-RBC |
| BXSB | SLE | Mouse | Yaa mutation (duplication of X chromosome containing *TLR7* gene on Y chromosome) |
| (NZW × BXSB)F1 | SLE, APS, ITP | Mouse | Anti-cardiolipin, anti-platelet |
| BXD2 | SLE, RA | Mouse | Lupus and inflammatory arthritis |
| SKG | RA | Mouse | *ZAP70* mutation |
| NOD | T1DM | Mouse | MHC (H-2$^{g7}$) similar to T1DM-predisposing HLA |
| BB | T1DM | Rat | Lymphopenia |
| **Genetically Modified** | | | |
| C1q ko | SLE | Mouse | Defective clearance of apoptotic cells |
| FcγRIIb ko | SLE | Mouse | Impair regulation of B cell and APCs |
| BAFF Tg | SLE | Mouse | Enhanced survival of B cells |
| TLR7 Tg | SLE | Mouse | Enhanced survival and activation of B cells and DCs |
| *Sanroque* mice (*roquin* gene) | SLE | Mouse | *Rc3h1* M199R mutation increases ICOS expression and Tfh cell expansion |
| miR-17-92 Tg | SLE | Mouse | miRNA-induced autoimmunity |
| K/BxN, TCR Tg | RA | Mouse | Arthritis mediated by anti-GPI |
| MBP-specific TCR Tg mice | MS | Mouse | Spontaneous autoimmune encephalomyelitis |
| Double Tg: anti-GP TCR and insulin promoter-GP (GP = LCMV glycoprotein) | T1DM | Mouse | Ignorant Tg T cells are activated by infection with LCMV, causing insulitis and diabetes |
| **Induced** | | | |
| TMPD (pristane)-induced autoimmunity | SLE | Mouse | IFN-α- and TLR7-dependent |
| Hg-induced autoimmunity | SLE | Mouse, rat | IFN-γ dependent |
| Chronic graft-versus-host disease | SLE | Mouse | Parent into F1 |
| Collagen-induced arthritis | RA | Mouse, rat | Autoimmunity to type II collagen |
| PG-induced arthritis | RA | Mouse | Autoimmunity to proteoglycan |
| Adjuvant arthritis | RA | Rat | Inflammatory arthritis induced by complete Freund's adjuvant or mineral oil |
| Citrullinated-protein-immunized DR4-IE transgenic | RA | Mouse | Autoimmunity to citrullinated-fibrinogen or enolase (human and bacterial) |
| EAE | MS | Mouse, rat | Autoimmunity to MBP, MOG, or PLP depending on MHC haplotype |
| EAT | Thyroiditis | Mouse, rat | Autoimmunity to thyroglobulin |
| EAMG | MG | Rat | Autoimmunity to acetylcholine receptor |

AIHA, Autoimmune hemolytic anemia; ALPS, angiolymphoproliferative syndrome; APC, antigen-presenting cell; APS, anti-phospholipid syndrome; DC, dendritic cell; EAE, experimental autoimmune encephalomyelitis; EAMG, experimental autoimmune myasthenia gravis; EAT, experimental autoimmune thyroiditis; GPI, glucose-6-phosphate isomerase; HLA, human leukocyte antigen; ICOS, inducible co-stimulator; IFN, interferon; ITP, idiopathic thrombocytopenic purpura; ko, gene knockout; LCMVB, lymphocytic choreomeningitis virus; MBP, myelin basic protein; MHC, major histocompatibility complex; miRNA, micro RNA; MOG, myelin oligodendrocyte glycoprotein; MS, multiple sclerosis; PG, prostaglandin; PLP, proteolipid protein; RA, rheumatoid arthritis; RBC, red blood cell; SLE, systemic lupus erythematosus; T1DM, type 1 diabetes mellitus; TCR, T cell receptor; Tfh, follicular helper T cell; Tg, transgenic; TMPD, 2,6,10,14-tetramethylpentadecane.

neuromuscular junction (acetylcholine receptor), muscle, heart, adrenal gland, bladder, stomach, liver, inner ear, kidney, and prostate tissues. In certain susceptible strains of rats, a progressive inflammatory erosive arthritis called adjuvant arthritis can also be induced by intradermal injection of complete Freund's adjuvant or by mineral oil components of Freund's adjuvant such as TMPD. Other induced models of arthritis include streptococcal cell wall and antigen-induced arthritis.[16] Arthritis characterized by synovial hyperplasia and ankylosis was reported in human leukocyte antigen (HLA)-DR4-IE transgenic mice immunized with human citrullinated fibrinogen or enolase.[31,32]

**TABLE 19-4** Multiple Tiers of Tolerance

| Type | Cell Type | Site | Mechanism |
|---|---|---|---|
| **Central Compartment** | | | |
| Central tolerance | T cells<br>B cells | Thymus<br>Bone marrow | Primarily deletion, anergy, possibly editing<br>Editing, anergy, deletion |
| **Peripheral Compartment** | | | |
| Immature B cell tolerance | Transitional 1 (T1) B cells | Periphery | Deletion, anergy upon activation |
| Peripheral anergy | T and B cells | Secondary lymphoid organs and peripheral tissue | Inadequate signal induces cell inactivation |
| Ignorance | T cells; maybe B cells | Peripheral and secondary lymphoid organs | Insufficient self-antigen or co-stimulation |
| Inaccessible self-antigen | T and B cells | Peripheral organs | Sequestration, crypticity |
| Regulation | T and B cells | Secondary lymphoid organs and site of inflammation | Suppression by regulatory cells via intercellular signals and cytokines |
| Clonal deletion after activation | T and B cells | Site of inflammation and secondary lymphoid organs | Apoptosis caused by a decline in survival factors |
| Cytokine deviation | T cells | Site of inflammation and secondary lymphoid organs | Differentiation toward less pathogenic Th subsets |
| Postsomatic hypermutation | B cells | Germinal center | Insufficient CD4 T cell help, deletion (via *Fas*) |
| Tissue resistance | B and T cells | Peripheral tissues | Inhibitory intercellular signals and cytokines |
| **Innate Mechanisms** | | | |
| PRR engagement required for activation | Innate cells | Site of inflammation | Simple mechanism for self-nonself discrimination |
| Suppression of adaptive immune responses | Immature and mature DC | Site of inflammation and secondary lymphoid organs | Delivery of inhibitory signals and activation of Treg |
| Clearance of apoptotic cells | Complement, phagocytes | Peripheral tissues | Removal of potential pro-inflammatory material and self-antigens |
| Complement mediated effects on adaptive responses | Lymphocytes, innate cells | Secondary lymphoid organs and peripheral tissue | Modulation of activation |

PRR, Pattern recognition receptor; Treg, regulatory T cell.

## TOLERANCE MECHANISMS

Increasing insights into mechanisms of self-nonself discrimination have emerged during the past six decades in parallel with growing knowledge of the immune system. Just over 50 years ago, Burnet and Medawar advanced the critical concept that tolerance was imposed by clonal deletion of self-reactive lymphocytes during early development—that is, central tolerance.[33,34] The subsequent discovery that mature B cells undergo somatic hypermutation in the periphery led to the hypothesis by Bretscher and Cohn that the production of autoantibodies might be impeded by the need for both B and T cell compartments to breach tolerance.[35] In 1975, while studying allogeneic responses, Lafferty and Cunningham posited that activation of T cells involved the passing of a second signal that need not be antigen-related, thereby implicating co-stimulation from antigen-presenting cells (APCs) as a critical factor in lymphocyte activation.[36] In 1987, the nature of the co-stimulation, or two-signal, requirement was further defined when Jenkins and Schwartz showed that engagement of antigen receptor alone without a second signal resulted in functional inactivation of T cells.[37] An elegant mechanism for self-nonself discrimination was then advanced by Janeway in 1989 when he hypothesized that APCs remain quiescent unless activated by the engagement of pattern recognition receptors (PRRs) by microbial products.[38] This concept was further extended by Matzinger in 1994 to a "danger model" that includes activation of the immune system by both foreign and endogenous factors associated with tissue stress and damage.[39] These models laid the foundation for the current, more complex view of self-nonself discrimination in which tolerance is imposed by both innate and adaptive immune systems through layers of mechanisms occurring at various stages throughout lymphocyte development and activation (Table 19-4).

### Clone-Specific Self/Nonself Recognition

In contrast to innate immune cells, which are activated primarily by hardwired microbial PRRs, lymphocytes have broad specificity and therefore self-nonself discrimination must be implemented at the clonal level. To achieve this objective, T and B cells utilize several mechanisms that can be grouped into three general strategies. First, the type of response is controlled by developmental stage. For example, immature lymphocytes respond to strong antigen receptor stimulation by cell death, whereas a similar signal in mature cells leads to activation. Through this mechanism, self-reactive clones are eliminated from the nascent lymphocyte repertoire before they can cause injury. Second, activation of mature lymphocytes requires, in addition to antigen receptor engagement, a second co-stimulatory signal, the absence of which results in anergy or cell death. For the most part, this requirement limits reactivity to self because co-stimulatory signals are largely provided by cells of the

innate immune system. Third, lymphocytes are fine-tuned in various ways by a fairly extensive list of modulating factors necessary for controlling self-reactive clones.[40-42] In B cells, but not T cells, this includes an inverse correlation of antigen receptor (membrane immunoglobulin [Ig]M) expression and ability to flux calcium with the degree of self-reactivity.[43]

Examples of defects affecting a broad range of other surface receptors on lymphocytes include those with prosurvival (IL-7R, BAFF receptor [BAFFR], and IL-2R), proapoptotic (TNF receptors [TNFRs], Fas ligand [FasL], and TNF-related apoptosis-inducing ligand [TRAIL]), co-stimulatory (CD28, CD40, and Toll-like receptors [TLRs]), differentiating (IL-12R, IL-4R, interferon γ receptor [IFNγR], IL-23R, retinoic acid receptor, transforming growth factor-β receptors [TGF-βRs], signaling lymphocyte activation molecule [SLAM]/SLAM-associated protein [SAP] family members, OX40, and inducible co-stimulator [ICOS]/ICOS ligand [ICOSL]), inhibitory (FcγRIIb, CD22, cytotoxic T lymphocyte–associated antigen-4 [CTLA4], and programmed cell death protein 1 [PD-1]), antigen receptor signal modulating (CD19 and CD45), and activating (SAP/SLAM family members) functions, and they have been shown to influence the development of autoimmunity.[10] Collectively, these self-nonself recognition mechanisms provide the basic cellular means by which the innate and adaptive immune systems render T and B cell clonotypes tolerant to self-antigens and resistant to autoimmune disease.

## The Innate System and Tolerance

Given its vital role in initiating and modulating adaptive immune responses, it is not surprising that the innate immune system strongly influences both tolerance and autoimmunity. Indeed, although its contributions have yet to be fully delineated, several ways in which self-tolerance is influenced by the innate arm have been defined.

First, activation of the innate immune system under normal circumstances typically requires engagement of microbial PRRs, which endow the immune system with a direct and simple way to distinguish foreign antigens from self-antigens.[44] PPRs recognize common structures on pathogens and also a few self-molecules, such as certain damage-associated molecular patterns (DAMPs)—for example, heat shock proteins[45]—which are released during cellular stress, injury, or death. PPRs can be classified by their location into the following types: secreted (e.g., collectins, pentraxins, and ficolins), transmembrane (e.g., TLRs, certain C-type lectin receptors, and N-formyl methionine receptors), and endosomal (e.g., TLRs) or cytosolic (e.g., retinoic acid inducible gene I [RIG-I]-like receptors, NOD-like receptors, and DNA receptors: IFI16, AIM2, and the cyclic guanosine monophosphate [GMP]–adenosine monophosphate [AMP] synthase–stimulator of interferon genes [STING] pathway).[46-48] The importance of this mechanism is illustrated by the finding that overexpression of TLR7 by spontaneous gene duplication or transgenic approaches promotes systemic autoimmunity.[49] This outcome occurs because certain PRRs, such as TLR7 and TLR9, which equally sense both foreign and self-nucleic acids, avoid significant exposure to endogenous nucleic acids by virtue of their location in subcellular compartments.[50] However, in the case of TLR7, overexpression makes it possible for normally substimulatory amounts of endogenous RNA to activate immune cells, thereby bypassing the usual requirement for microbial exposure.

Second, some cells of the innate immune system actively suppress adaptive immune system activation under certain conditions. For example, both immature and mature dendritic cells (DCs) have been shown to promote tolerance by inducing CD4 T regulatory (Treg) cells and other mechanisms.[51,52]

Third, failure of the rapid non-inflammatory clearance of apoptotic cells, another critical function of the innate immune system,[53,54] can result in an increased supply of self-antigenic material including nucleic acids, secondary necrosis, and release of pro-inflammatory factors, leading to systemic autoimmunity.[55] Accordingly, deficiencies in several key apoptotic cell clearance molecules are associated with autoimmunity, including (1) the Tyro3-Axl-Mer receptors on phagocytes that bind, through Gas6 or protein S, the exposed phosphotidylserine (PS) on apoptotic cells[56], (2) the milk fat globule–epidermal growth factor (EGF) 8 (MFG-E8) protein that bridges the αvβ3 integrin on phagocytes and PS on apoptotic cells,[57,58] (3) Tim4 expressed on the surface of resident macrophages that binds PS,[59] (4) the 12/15 lipoxygenase that controls which macrophage subpopulations phagocytize apoptotic cells,[60] and (5) natural IgM, C1q, or C1q receptor (SCARF1) that bind to and enhance clearance of apoptotic cells.[61-64]

Fourth, several complement components have been directly implicated in autoimmunity. For example, SLE is associated with deficiencies of proximal components of the classical pathway, including C1q, C4, and C2. Although the mechanism for this association is uncertain, both defective clearance of apoptotic material/immune complexes and a shift in the activation threshold of lymphocytes have been suggested.[65] Another example is that deficiency of CD55 (or decay-accelerating factor), a cell surface protein that restricts complement activation, is associated with enhanced T cell responses and exacerbation of neuroinflammation and lupus in animal models.[66,67]

Fifth, the innate system could be a major source of self-antigenic material. For example, neutrophil extra-cellular traps (NETs), the nuclear material–containing weblike structure extruded by neutrophils to combat bacterial infection, contain a compelling collection of modified autoantigens, but thus far their role in patients remains to be firmly established.[68] Thus, at many levels, the innate immune system plays a critical role in maintaining tolerance and controlling autoimmunity.

## T Cell Tolerance

T cells are critical players in not only achieving but also fine-tuning tolerance to a high degree of specificity. Several mechanisms have been identified that can be divided into three main areas: central tolerance wherein T cells first acquire their antigen receptor, peripheral tolerance where T cells encounter self-antigens not present in the thymus, and postactivation regulation wherein activated and expanded T cell clones are returned to their resting state. Central tolerance, as alluded to earlier, is

imposed on T cells with self-reactive specificities during thymocyte development by mechanisms utilizing primarily deletion, to a lesser extent anergy, and possibly receptor editing of the TCR α chain.[69,70] This process, although highly effective, is not completely efficient, and T cells with autoreactivity—primarily those with intermediate to low affinity to self or that recognize self-antigens poorly expressed in the thymus—emigrate in significant numbers. This leakiness is probably necessary to generate a broad repertoire, but it then creates vulnerability to autoimmunity and necessitates peripheral tolerance mechanisms.

In the periphery, multiple mechanisms for avoiding autoreactivity have been identified. Among these, a common explanation is that most self-antigens are not accessible to trigger a response, a situation that can be caused by low abundance, specific characteristics of the self-antigen, or location. This mechanism is supported experimentally by the finding that T cells expressing a transgenic TCR to certain tissue-specific antigens are not deleted or activated, nor do they cause autoimmune disease. Yet, these so-called "ignorant" T cells are fully functional and respond to self-antigen when presented in a conventional context.[20,71] For a few self-antigens, such as those expressed in the anterior chamber of the eye, central nervous system (CNS), or other so-called immunologic privileged sites—as originally defined by their ability to accept allograft transplants—resistance to self-reactivity is also partly from anatomic sequestration caused by limited access of blood-borne cells and the absence of conventional lymphatic drainage.[72] The latter is important because T cells are typically first activated in secondary lymphoid organs and subsequently migrate to target organs where reactivation by local APCs and the production of pro-inflammatory factors leads to tissue damage.[73] Anatomic sequestration alone, however, is not sufficient for tissues to support immunologic privilege and, as will be discussed later, such sites employ a host of additional local mechanisms.[74,75]

Another peripheral mechanism is the aforementioned two-signal paradigm in which T cell activation requires both TCR engagement and a co-stimulatory signal usually provided by CD28. Because the two ligands for CD28, CD80, and CD86 are primarily expressed at high levels on activated professional APCs, presentation of self-antigen by quiescent APCs would lead to tolerance. Indeed, immature DCs promote tolerance in this manner by constitutively presenting low doses of self-antigen on major histocompatibility complex (MHC), resulting in cell death or anergy of the corresponding T cells.[76]

Peripheral tolerance is also maintained by active suppression via immunoregulatory cells of the immune system, among which $CD4^+$ Tregs are the best characterized.[77-80] They constitute a distinct αβ–T cell subset generated in the thymus (natural Treg [nTreg]) or are differentiated in the periphery from naïve or mature $CD4^+$ T cells exposed to TGF-β (induced Treg [iTreg]) and developmentally induced by the forkhead box P3 (FOXP3) transcription factor. $CD4^+$ Tregs typically express high levels of the IL-2 receptor component, IL-2Rα (CD25), and require IL-2 for survival. Tregs participate in every adaptive immune response, are critical for maintaining the proper level of immune response, and are activated at the same time as conventional T cells. They are thought to suppress the magnitude of the response by initially downregulating DC function and then inhibiting T cell activation by competing for IL-2, producing immunosuppressive cytokines such as TGF-β, IL-10, and IL-35, and by cell-cell inhibitory interactions that lead to cell killing or the induction of negative signals.[81] These inhibitory actions suppress T cells that are in proximity to Treg cells regardless of their antigen specificity.[82] Other T cells with regulatory activity in autoimmunity, including Tr1, CD8 Treg, Qa-1/HLA-E–restricted CD8 T cells, and γδ T cells, have been described but are less well characterized.[83-87]

Tissues themselves also employ mechanisms that suppress self-reactivity and contribute to the establishment of immune privilege.[74,88-90] These tissues can be considered to comprise three general categories: First, certain tissues are decorated with cell surface inhibitory molecules, such as the proapoptotic FasL and TRAIL, lymphocyte inhibitory and Treg promoting PD-L2, and complement regulatory proteins, CD55 and CD46, that can potentially eliminate or impede the activation of autoreactive T cells. Second, soluble inhibitors of inflammation and immune activation are secreted by particular tissues. Notably, in the aqueous humor of the eye, there is a broad spectrum of such factors that include TGF-β, α–melanocyte-stimulating hormone, vasointestinal peptide, calcitonin gene–related protein, somatostatin, macrophage inhibitory factor, and complement inhibitors. Third, lymph node resident stromal cells have been shown to induce tolerance of $CD8^+$ T cells that recognize peripheral tissue-restricted self-antigens.[91,92] Thus it has been proposed that stromal cells in lymph node and tissues may serve to provide a means to eliminate T cells that bind to tissue-restricted antigens not expressed in the thymus. Fourth, the anterior chamber of the eye elicits a unique type of altered immune response through a complex multistep process termed "anterior chamber–associated immune deviation" (ACAID) that leads to a dampened, less tissue-destructive response.[74,90,93] Although ACAID was long thought to be important for tolerance, it has recently been argued that its primary function may be to modulate the immune response so the eye can respond to infection without damaging its integrity.[94]

Another possible peripheral mechanism is immune deviation wherein polarization away from a predisposing cytokine pattern—such as from a Th1 to a Th2 profile—by administering or blocking specific cytokines suppresses the development of autoimmune disease.[95] Similarly, activation of natural killer (NK) T cells with α-GalCer, which induces IFN-γ production, is associated with dampening of the adaptive Th1 and Th17 effector responses and protection from experimental autoimmune uveitis.[96] In these models, autoreactive T cells are activated but do not produce the pro-inflammatory factors necessary for tissue damage.

In addition to central and peripheral tolerance, the immune system must also avert autoimmunity by suppressing or eliminating T cells after their activation or expansion. This regulation is mediated by several processes, including upregulation of inhibitory receptors such as CLTA4 and PD-1,[97] expression of proapoptotic receptors such as Fas, synthesis of metabolic enzymes such as indoleamine-2,3-dioxygenase (IDO),[98] and release of intracellular proapoptotic factors such as Bim. Deficiencies of such mediators that control the magnitude of T cell

responses are associated with severe expansion of lymphocyte populations and with varying degrees of autoimmunity.

## B Cell Tolerance

B cells are not only required for antibody production but serve as potent APCs for T cells and follicular DCs and can also act in regulation.[99] Moreover, depletion of B cells with rituximab has shown promise even in autoimmune diseases considered to be mediated by T cells such as T1DM[100] and MS.[101] Therefore, substantial interest exists in defining both mechanisms of B cell tolerance and the specific role of B cell tolerance in autoimmune disease.

Before discussing specific tolerance mechanisms, however, it should be emphasized that the fate of B cell antigen receptor (BCR) after cross-linking is highly dependent on developmental stage, context and strength of signal, and the nature of the antigen, probably more so than for T cells because B cells are subjected to less stringent selection during central tolerance. Several checkpoints considered important for controlling autoreactive B cells and maintaining self-tolerance have been identified and include many central and peripheral mechanisms similar to those described for T cells, as well as a few additional ones.

Central tolerance of B cells takes place in the bone marrow during pre-B to immature B cell transition as they express rearranged Ig genes on their surface.[102] It appears that the dominant mechanism for B cells with high affinity to membrane-bound self-antigen is receptor editing (replacement of light [L] chain) and, to a lesser extent, deletion, whereas soluble self-antigens induce both receptor editing and anergy.[103,104] Anergic B cells are detectable in the periphery as an $IgD^{+}IgM^{-}$ population[105] or in mice as splenic transitional 3 (T3) B cells.[106] They are short-lived at least in part because they downregulate the BAFFR, which is required for their survival, putting them at a competitive disadvantage with other immature B cells, and they are less able to enter B cell follicles.

In the periphery, the earliest tolerance checkpoint occurs at the transitional 1 (T1) B stage over a 2-day interval before maturation to T2 and later naïve B cell subsets.[102,107-109] T1 B cells are the immediate bone marrow emigrant population, retain an immature phenotype, and are dependent on BAFF for survival. Importantly, they undergo apoptosis and not activation when stimulated, which results in deletion of B cells that recognize peripheral self-antigens not expressed in the bone marrow compartment. Thus, this mechanism, which is unique to B cells, essentially represents an extension of central tolerance to the periphery. Self-reactive B cells can also downmodulate their surface IgM,[43] which allows them to escape deletion and affords the host a broader repertoire despite the risk of autoimmunity.

Other peripheral tolerance mechanisms are achieved in much the same way as those previously described for T cells but differ qualitatively as a result of distinct differentiation pathways and differences in antigen recognition by B cells and T cells—that is, BCRs can bind to virtually all tertiary structures, whereas TCRs are restricted to recognizing self-MHC/peptide complexes on host cell surfaces. Accordingly, B cells can be ignorant of their corresponding self-antigen because of insufficient quantity or access[21] or can undergo anergy and ultimately cell death if engagement of the BCR occurs without co-stimulation, that is, two signals.[110]

Another notable checkpoint occurs during T-dependent immune responses as B cells undergo affinity maturation in germinal centers (GCs) and acquire new specificities that may include self-reactivity. Evidence suggests that tolerance at this juncture is often defective in autoimmune diseases, because most autoantibodies have acquired autoreactivity through somatic hypermutation and are class-switched,[111-113] both of which are indicative of GC maturation. Although recent studies have provided significant insights into GC processes involved in the selection of B cell clones with high affinity to foreign antigens, the manner in which tolerance of class-switched autoreactive B cells is achieved remains less well defined. Nevertheless, the strongest evidence suggests that (1) autoreactive B cells compete poorly for the cognate T cell help essential for GC B cell survival because the autoreactive BCR would bind less well to the original antigen, resulting in less internalization of antigen for processing and presentation to T cells,[114-116] and (2) B cells that acquire BCRs with reactivity to high-density membrane self-antigens are deleted by a Fas-dependent mechanism.[117,118]

# THEORIES OF AUTOIMMUNITY

Development of autoimmune diseases is influenced by genetic and, to varying degrees, environmental, gender, and other factors, with current evidence supporting a model in which genetic predisposition is required (Figure 19-1). Therefore, theories of autoimmunity and loss of tolerance are closely intertwined with genetic influences. In addition, such theories must also explain how tolerance is breached when autoimmunity is induced in otherwise healthy animals. Upon taking both these factors into account and applying a reductionist perspective, theories of autoimmune disease can be consolidated into two main mechanisms representing separate ends of a continuum, with most diseases having some elements of both. On one end, loss of tolerance and consequent autoimmune disease is

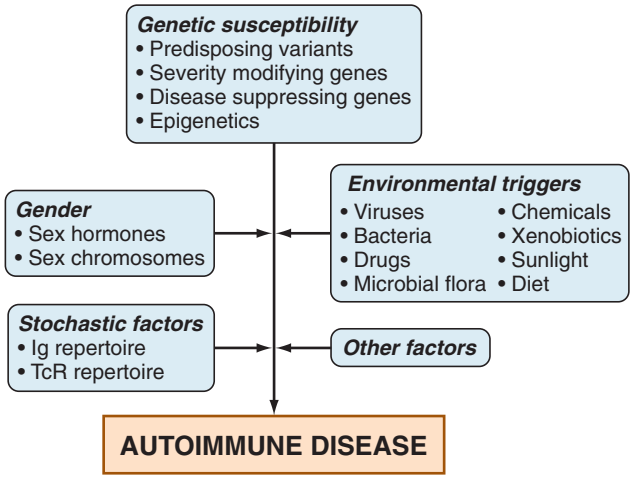

**Figure 19-1** Etiology of autoimmune diseases. Autoimmune diseases are usually caused by the additive effects of autoimmunity-promoting environmental, gender, and other factors superimposed on significant underlying genetic predisposition. IG, Immunoglobulin; TcR, T cell receptor.

**TABLE 19-5** Mechanisms of Autoimmunity

| Examples | Disease | Mechanism |
|---|---|---|
| **Defective Tolerance** | | |
| **Central Defects** | | |
| *AIRE* deficiency | APECED syndrome | Failure to delete autoreactive T cells because of reduced expression of peripheral antigens in thymus |
| *ZAP70* deficiency | Inflammatory erosive arthritis (mice) | Defective T cell activation and thymic selection |
| **Peripheral Defects** | | |
| FAS/FASLG deficiency | ALPS | Defective apoptosis |
| Rc3h1 (M199R) mutation | Lupus (mice) | Increased ICOS on Tfh cells promotes their expansion |
| TREX1 (DNase II) deficiency | Aicardi-Goutières syndrome, chilblain lupus | Accumulation of intra-cellular DNA induces IFN-α production |
| FOXP3 deficiency | IPEX syndrome | Absence of Treg cells |
| PD-1 deficiency | Lupus, myocarditis (mice) | Defective peripheral tolerance of T cells |
| **Activation of Nontolerant Lymphocytes** | | |
| Penetrating injury | Sympathetic ophthalmia | Release of self-antigen in an inflammatory milieu |
| Coxsackie B virus infection | T1DM (mice) | Infection mediated release of self-antigen in an inflammatory milieu |
| Immunization with self-antigen and strong adjuvant | EAE (mice) | Activation of ignorant T cells |
| Citrullination of proteins | RA | Generation of neo self-antigens |
| Altered structure of collagen IV caused by sulfilimine bonds | Goodpasture's syndrome | Formation of conformational neo self-antigens |
| Cross-reactivity of group A streptococcal and cardiac antigens | Rheumatic fever | Molecular mimicry |
| Lymphopenia caused by disease-associated IL-21 production | T1DM (NOD mice) | Lymphopenia-induced homeostatic proliferation |

AIRE, Autoimmune regulator; ALPS, autoimmune lymphoproliferative syndrome; APECED, autoimmune polyendocrinopathy candidiasis ectodermal dystrophy; DNase, deoxyribonuclease; EAE, experimental autoimmune encephalomyelitis; ICOS, inducible co-stimulator; IFN, interferon; IL, interleukin; IPEX, immune dysregulation, polyendocrinopathy, enteropathy X-linked; NOD, nonobese diabetic; PD-1, programmed cell death protein 1; RA, rheumatoid arthritis; T1DM, type 1 diabetes mellitus; Tfh, follicular helper T cell; Treg, regulatory T cell.

caused by genetically imposed defects in central and/or peripheral tolerance mechanisms, whereas on the other end, autoimmunity arises from the conventional immune response to self-antigens for which tolerance is normally incompletely established (Table 19-5). In general, most systemic autoimmune diseases are caused by tolerance defects, whereas organ-specific diseases can be mediated by either mechanism.

## Defective Tolerance

Although it can be inferred that loss of tolerance underlies autoimmunity, the specific tolerance defects causing common autoimmune diseases and polygenic animal models have been difficult to delineate, presumably because of modest defects at multiple checkpoints. Nevertheless, studies of monogenic human autoimmune diseases and animal models have identified a wide range of defects in the various layers of central and peripheral tolerance. Such defects are caused by diverse genetic abnormalities and are mediated by a variety of lymphoid and nonlymphoid cell types. A few representative examples will be discussed.

Defects in central tolerance have long been suspected to cause autoimmunity because of the well-documented role of central tolerance in eliminating nascent self-reactive lymphocytes, but until relatively recently, solid evidence for this mechanism was lacking. A breakthrough came from the discovery that mutations in a transcription factor, autoimmune regulator (AIRE), was the cause of autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED), a rare inherited disease associated with T cell–mediated autoimmune destruction of multiple endocrine organs.[119-121] *Aire*-deficient mice developed a similar syndrome caused by the reduced expression of thousands of mostly peripheral tissue genes in the thymic medullary epithelium and consequent failure to eliminate T cells recognizing those gene products. Evidence suggests that AIRE achieves this selectivity by binding to certain repressive transcription complexes such as MBD1-ATF7ip that target specific methylated cytosine-phosphatidyl-guanine (CpG) dinucleotides in genetic regions encoding tissue-specific antigens. Thus, it appears that the main function of AIRE is to prevent autoimmunity by deleting T cells that recognize peripheral tissue self-antigens.

Another example of altered thymic selection leading to autoimmunity, in this instance caused by an intrinsic defect in the T cells, is the aforementioned ZAP70 arthritis model.[122] Here, a function-impairing mutation in the C-terminal SH2 domain of ZAP70, a Syk family tyrosine kinase activated by the TCR complex ζ-chain, reduces TCR signaling, causes defective conventional T cell and nTreg development in the thymus, and seemingly enhances positive selection of autoreactive T cells.[123] Interestingly, using several ZAP70 mutants, it was shown that susceptibility to arthritis was altered by only slight differences in ZAP70-mediated signaling strength.[123,124]

For B cells, major defects in central tolerance leading to autoimmunity have been more difficult to prove, and no AIRE-like equivalent has been discovered, presumably because immature B cells continue the selection process for a couple of days after egress from the bone marrow, allowing direct exposure to peripheral antigens. Nevertheless, defective central tolerance of B cells in autoimmunity has been suggested by the finding of a higher frequency of naïve mature B cells with self-reactivity in patients with SLE and RA.[125-127]

In the periphery, FAS deficiency provides an example of defective peripheral tolerance promoting autoimmunity.[128] FAS is a proapoptotic surface receptor that plays a critical role in maintaining immunologic homeostasis by eliminating undesired cells. Defects in FAS cause autoimmune lymphoproliferative syndrome (ALPS, also called Canale-Smith syndrome) and, in mice, lymphoproliferative (lpr) disease, both of which exhibit massive enlargement of secondary lymphoid organs caused mainly by the accumulation of a normally rare, so-called "double-negative" subset of T cells lacking both CD4 and CD8 co-receptors, along with a variety of autoimmune manifestations. Lpr mice are defective in eliminating B cells that acquire self-reactivity in the periphery, a process that typically occurs in the GC during somatic hypermutation.[117] Similar abnormalities are found in humans and mice with defects in the ligand for FAS (FASLG).[129]

Peripheral tolerance is also breached by overexpression of the co-stimulatory molecule ICOS on T follicular helper (Tfh) cells in sanroque mice. These mice have a point mutation in the *Rc3h1* gene, a RING-type ubiquitin ligase that impairs its ability to degrade ICOS mRNA.[130] Increased expression of ICOS promotes the expansion of Tfh cells and GCs, production of IL-21, and autoimmunity.[131]

An example of a lymphocyte-extrinsic cause for loss of tolerance and autoimmunity is deficiency in the 3′ repair exonuclease 1 (TREX1, deoxyribonuclease [DNase] III). Loss-of-function mutations in TREX1 have been implicated in Aicardi-Goutières syndrome, a rare progressive encephalopathy associated with elevated IFN-α levels in the cerebrospinal fluid, and chilblain lupus, a rare form of SLE characterized by painful bluish-red inflammatory skin lesions typically affecting areas exposed to cold temperatures.[132,133] Autoimmunity is thought to be caused by the intra-cellular accumulation of single-stranded DNA (ssDNA) derived from endogenous retro-elements normally degraded by TREX1, resulting in the activation of the intra-cellular DNA sensor STING and consequent overproduction of IFN-α.[134-136] Intriguingly, oxidized DNA, which is abundant in NETs and in ultraviolet skin lesions, is resistant to TREX1 degradation and can promote STING activation and type I IFN production,[137] suggesting that the TREX1 pathway may play a more general role in SLE pathogenesis. The importance of DNA disposal in lupus has been further illustrated by the association of DNase I deficiency with development of lupus in humans and mice.[138,139]

Defective regulation can also result in loss of tolerance and autoimmune disease, as illustrated by the absence of Tregs.[140,141] In humans, monogenic deficiency of the *FOXP3* gene, which is required for Treg development, is associated with the immune dysregulation, polyendocrinopathy, enteropathy X-linked (IPEX) syndrome, a severe systemic autoimmune disease associated with diarrhea, eczematous dermatitis, and endocrinopathy that is usually fatal within the first year. T1DM, autoimmune cytopenias, and nephritis are among other less common autoimmune manifestations of this syndrome. Similar findings are observed in scurfy mice, which have a spontaneous function-impairing mutation of *Foxp3*.

## Autoimmunity Caused by Activation of Intolerant or Partially Tolerant T Cells

The other main theory is that autoimmunity develops through the conventional activation of self-reactive T cells that have not been deleted in the thymus and remain oblivious to the corresponding self-antigen after emigration. Such ignorant T cells, commonly found in the periphery of both healthy humans and animals, can be activated by antigen presented by professional APCs in the context of an innate inflammatory milieu. Once activated, T cells are able to gain access to virtually all tissues and, when activated again locally, can elaborate pro-inflammatory factors, causing tissue damage.[73] Breach of tolerance by this mechanism is most often associated with organ-specific diseases, presumably because tissue-specific antigens are less likely to be expressed in the thymus. This theory is supported by the finding that type 1 diabetes is prevented in BB rats and NOD mice by intrathymic transplantation of pancreatic islets[142,143] or inhibited in NOD mice by intrathymic administration of glutamic acid decarboxylase (GAD), a major β-islet autoantigen in this model.[144,145] Similarly, EAE can be prevented by intrathymic administration of either the immunizing antigen, myelin basic protein, or its major encephalitogenic epitope,[146] and autoantibody production can be delayed in lupus-prone mice after intrathymic injections of polynucleosomes.[147] Taken together, these data support the concept that autoimmunity can be caused by the activation of lymphocytes to self-antigens for which there was incomplete central tolerance. This mechanism is similar to the mechanism underlying the APECED syndrome caused by AIRE deficiency, but in this instance central tolerance is not known to be defective.

Breach of tolerance by ignorant lymphocytes has been shown to depend on many factors, including (1) the nature of the self-antigen, (2) the extent of exposure to antigen, (3) antigen receptor affinity, (4) frequency of autoreactive lymphocytes, (5) types and levels of co-stimulatory molecule expression, (6) cytokine and chemokine profiles, and (7) presence of inflammation.[20,148-154] It should be also emphasized that despite the presence of lymphocytes that recognize self-antigen, under normal conditions, peripheral tolerance mechanisms are difficult to overcome. Consequently, although the experimental autoimmune models are highly reproducible, they require supra-physiologic amounts of self-antigen, strong adjuvant, specific MHC haplotypes, and a susceptible background to break tolerance. This finding is consistent with the fact that autoimmunity does not develop in most individuals and speaks to the robustness of the tolerance process that must be overcome. Although it is difficult to prove which of these mechanisms are applicable in patients, they provide frameworks for understanding how autoimmunity can develop, along with guidance in devising interventions.

Similar to immune responses in general, key factors for the initiation of autoimmunity are innate inflammatory and co-stimulatory factors that promote the initial activation and expansion of naïve autoreactive lymphocytes. This mechanism is thought to contribute to the autoimmune response by the release of self-antigens after cell damage or death, increased MHC/peptide expression, upregulation of co-stimulatory factors, and activation of professional APCs.[149,150,155] Indeed, moderate to severe tissue necrosis is often associated with some evidence of autoreactivity, although this condition rarely progresses to autoimmune disease.[156,157] In autoimmune diseases, chronic cell and tissue injury and the continual release of self-antigens under conditions favorable for antigen presentation and co-stimulation promotes epitope spreading and the activation of an expanding repertoire of lymphocytes that recognize autoantigens beyond the initiating autoantigen.[158,159] This process is thought to at least partially account for the often progressive course of autoimmunity. Overall, these and other findings support the theory that, under certain conditions such as infection or trauma, self-antigens are released and, in the presence of inflammatory factors and an activated innate immune system, there is triggering and expansion of previously ignorant self-antigen–recognizing lymphocytes that can lead to autoimmune disease.

In addition to the release of sequestered self-antigens, the initial activation of non-tolerant lymphocytes has been postulated to occur in several other ways. Some investigators have suggested that the initial response may be directed toward certain determinants[160,161] based on the concept of "crypticity," essentially the presence of a hierarchy of dominant and cryptic epitopes on a protein because of differences in binding affinity to the MHC, protein processing, preference for presentation by different APCs, and the repertoire of epitope-specific T cells.[159] It is therefore posited that during thymic selection, T cells that engage the few dominant epitopes are eliminated, whereas those recognizing the less antigenic but more abundant cryptic epitopes are spared. The latter T cells then emigrate to the periphery, where they can be activated by the corresponding cryptic epitope under certain inflammatory conditions.

Another mechanism by which self-antigens can activate nontolerant lymphocytes is through the production of neo self-antigens after post-translational or chemical modifications. A prominent example of this mechanism is the formation of citrullinated proteins caused by the deimination of arginine residues by peptidylarginine deiminase (PADI) enzymes. Several citrullinated proteins are not only major targets of autoantibodies in a subset of RA but are thought to play a significant role in disease pathogenesis.[162-164] Deficiency of protein L-isoaspartate O-methyltransferase (PIMT), which catalyzes the repair of isoaspartyl (isoAsp) proteins formed by the spontaneous conversion of aspartic acid to its isoAsp derivative, has also been shown to result in accumulation of isoAsp proteins and development of lupus in a mouse model.[165] Furthermore, in the PL/J model of EAE, acetylation of the encephalitogenic Ac1-11 peptide of myelin basic protein (MBP) is required for T cell activation even though unmodified peptide binds to MHC.[166] These and other studies suggest that protein modifications can generate new epitopes either directly by creating new structures such as citrulline or indirectly by altering MHC binding or modifying sites of peptide processing to produce new and/or cryptic self-peptides.[167]

Neo self-antigens can also arise from changes in overall structure—for example by the formation of immunogenic IgG-containing immune complexes from nonantigenic soluble monomeric IgG, which can induce rheumatoid factors, antibodies to the Fc portion of IgG.[168,169] Likewise, in Goodpasture's disease, a configuration change in type IV collagen due to sulfilimine bonds produces a neotarget for pathogenic autoantibodies, a mechanism coined *conformeropathy*.[170]

Another potential mechanism for triggering autoimmunity in susceptible persons is lymphopenia-induced homeostatic expansion of T cells.[171,172] Expansion occurs because of greater availability of survival-promoting cytokines (IL-7 and IL-15) that, when combined with low-affinity engagement of the TCR to self-peptide/MHC, induces low-grade proliferation without full activation. It was therefore hypothesized that the requirement for self-reactivity could, after repeated rounds of lymphopenia, result in the preferential expansion of autoreactive T cells and, consequently, autoimmunity.[171] This hypothesis is supported by the presence of lymphopenia in persons with certain autoimmune diseases, such as SLE and RA, autoimmune manifestations in some primary immunodeficiencies with lymphopenia, and several experimental autoimmune models.

In addition to self-antigens, foreign antigens with sufficient sequence or structural similarity can cross-activate nontolerant self-recognizing T (and B) lymphocytes, a mechanism termed *molecular mimicry*.[173] For T cells, several findings support this possibility: (1) cross-reactivity requires only short peptide lengths of 8 to 15 amino acids; (2) T cell recognition is highly degenerate, depending on only a few key amino acid residues, and it is possible to have mimotopes with no identical amino acids at any position[174,175]; (3) estimation that a single T cell, despite requiring anchor residues to bind the HLA, can react with $10^4$ to more than $10^8$ different peptides[176]; (4) MBP-specific T cells cloned from patients with MS can be stimulated by diverse microbial peptides[177,178]; and (5) infection with a modified Theiler's virus expressing a foreign cross-reactive peptide (*Haemophilus influenzae* protease IV protein that shares only 6/13 amino acids) induced T cells against a myelin protein, proteolipid protein (PLP), resulting in autoimmune CNS disease.[179] To date, however, no compelling evidence exists to connect a specific microbial T cell mimotope to any autoimmune disease.[180,181]

In contrast, fairly good evidence indicates that molecular mimicry affects self-reactive B cells in a few autoimmune diseases. The best examples include cross-reactivity of (1) bacterial adhesin FimH with lysosome-associated membrane protein 2 (LAMP-2) in anti-neutrophil cytoplasmic antibody (ANCA)-positive pauci-immune focal necrotizing glomerulonephritis[182]; (2) group A streptococcal carbohydrate epitope, N-acetyl glucosamine, and M protein with cardiac myosin in rheumatic fever[183]; and (3) *Campylobacter jejuni* lipo-oligosaccharide with ganglioside GM1 on peripheral nerves in the acute motor axonal neuropathy subtype of Guillain-Barré syndrome because of an identical determinant, Gal β1–3 GalNAc β1–4 (NeuAc α2-3) Galβ.[184,185] Overall, however, although molecular mimicry is an attractive hypothesis, supportive evidence for most autoimmune diseases is lacking. Whether this situation is because of

technical issues that impede detection, such as multiple mimotopes from diverse sources, diverse HLA haplotypes, and the considerable plasticity of the T cell receptor, or whether mimicry is an uncommon cause of autoimmune disease remains an open question.

## IMMUNOLOGIC MECHANISMS OF TISSUE INFLAMMATION AND DYSFUNCTION

The same effector mechanisms used by the immune system to neutralize pathogens are exploited in autoimmunity to inflict a wide range of deleterious effects on self-molecules, cells, and tissues. These mechanisms have been broadly grouped into hypersensitivity types II to IV, which encompass antibody-, immune complex–, and T cell–mediated processes, respectively (see Table 19-2).

In type II reactions, pathologic autoantibodies bind to self-antigens primarily located on cell surfaces or in tissues and mediate autoimmune disease by three general mechanisms: (1) altering the function of the target antigen, (2) promoting cell injury or death, and (3) inducing inflammation. Blocking or enhancing self-molecule function represents a special kind of type II hypersensitivity response in which autoantibodies alone are sufficient to effect autoimmune manifestations. Examples include the agonist anti–thyroid-stimulating hormone (TSH) receptor antibodies in Graves' disease that stimulate thyrocyte growth and production of thyroid hormone, the anti-acetylcholine receptor antibodies that block neuromuscular transmission in myasthenia gravis, and anti-β2-glycoprotein I antibodies in anti-phospholipid syndrome that alter the regulation of anticoagulant activity.[186] Direct cell injury or death is mediated by the binding of IgM or IgG to surface antigens, leading to cell lysis directly by complement activation or to phagocytosis via interaction of deposited C3 fragments with CR1 and CR3 receptors. Bound IgG also promotes phagocytosis through its interaction with Fc receptors. Examples include autoimmune hemolytic anemia, idiopathic thrombocytopenia, and autoimmune neutropenia. Finally, antibodies bound to tissue antigens promote inflammation by activating complement, which generates the chemoattractant C5a and leukocyte-activating C3 fragments, and by FcγR binding, which activates immigrating leukocytes such as neutrophils and macrophages, as well as tissue resident mast cells and basophils. These cells produce proinflammatory factors that further expand the inflammatory response by recruiting and then activating additional circulating leukocytes.

Type III responses are caused by abnormal deposition of immune complexes of IgG antibody and soluble antigen in tissues. Such complexes, which also contain bound C3 complement fragments, are normally cleared from the circulation by complement receptors on red blood cells (RBCs) and by complement receptors and FcγRs on mononuclear phagocytes and platelets. However, this clearance can be overwhelmed under certain conditions such as overabundant production or immune complexes composed of excess antigen wherein less antibody coverage reduces complement deposition and aggregation of Fc regions, leading to less efficient clearance. Once deposited in tissues, immune complexes initiate, through complement activation and FcγR binding, the same inflammatory cascades as type II responses. SLE and RA are autoimmune diseases mediated by this mechanism.

Type IV hypersensitivity encompasses cell and tissue injury mediated by activated T cells through their cytolytic activity in the case of CD8 T cells or the production of pro-inflammatory factors primarily by the CD4 subset. Apart from direct evidence of this mechanism in animal models using approaches that are not feasible in human studies, indirect evidence supporting this mechanism includes a higher frequency of autoreactive T cells with effector function in patients with autoimmune diseases, immunopathologic findings similar to T cell–mediated autoimmune models, and inhibition with T cell–blocking agents such as cyclosporin A.[187] T1DM and MS are examples of type IV reactions.

It should be mentioned that these classifications are general, and for some diseases, the underlying effector mechanism may be more complex. In RA, for example, the mechanism responsible for injury or dysfunction probably involves more than one hypersensitivity type,[188,189] whereas in others, such as SLE, different clinical manifestations are mediated by different mechanisms; for example, anti-neuronal antibody-mediated CNS disease is a type II process, whereas glomerulonephritis is a type III process.[190-193] Finally, for diseases such as dermatomyositis and systemic sclerosis, the type of mechanism mediating tissue injury remains to be defined.

## PATHOPHYSIOLOGY OF AUTOIMMUNE RHEUMATIC DISEASES

Although the general principles underlying loss of tolerance and autoimmunity provide a useful conceptual foundation, the actual pathophysiologies suggested by the few better-defined autoimmune diseases are likely to also employ specific and unique mechanisms. Two notable examples of this phenomenon are the pathophysiology of anti-nuclear antibody production in SLE and arthritis in RA. These examples will be briefly discussed in the context of their broader significance to autoimmune diseases.

Recent findings suggest a model of SLE pathophysiology that provides a mechanism explaining why anti-nuclear antibodies are virtually always present in lupus despite substantial genetic and clinical heterogeneity.[49,194] First, autoreactive B cells are activated when self-reactive BCRs bind to nucleosomes or ribonucleoprotein (RNP) and internalize them into the endolysosome compartment, where the released nucleic acids engage TLR7 and TLR9 and provide a second signal. Such activated B cells act as potent APCs for T lymphocytes and after class-switch recombination produce IgG autoantibodies. Next, immune complexes form by the binding of these autoantibodies to material containing nucleic acid activate plasmacytoid DCs (pDCs) and DCs after their internalization via FcγRIIA (FcγRIII in mice) and then engagement of TLRs by nucleic acids. Elaboration of lupus-promoting cytokines such as type I IFN and BAFF by pDCs and DCs, as well as enhanced antigen presentation, are thought to further drive loss of tolerance, activation of autoreactive B cells, and autoantibody production, thereby resulting in an amplification loop. Thus, in persons susceptible to lupus, confinement of nucleic acid–binding TLRs to endolysomes is not enough of a barrier to

block their activation by normally innocuous amounts of self-nucleic acids. This mechanism provides an explanation for the high prevalence of autoantibodies in SLE that either bind to nucleic acids or antigenic cargoes containing nucleic acids, such as DNA, nucleosomes, RNP, myeloperoxidase (ANCA), and even RBCs, or that exhibit cross-reactivity to such antibodies. Importantly, this explanation suggests the possibility that other autoimmune diseases might also be mediated by specific PRRs.

The pathophysiology of RA also involves common and specific pathways that together promote inflammatory synovitis in roughly three phases,[195-199] which is best described in the HLA-DR1*401 (DR4) anti-citrullinated protein antibody $(ACPA)^+$ subset of patients with RA, who have greater disease severity. The initial pre-clinical phase that can occur years before the onset of arthritis is postulated to involve the activation of T cells and B cells at extra-articular inflammatory sites where CCPs are produced in part by the release of peptidylarginine deiminase from apoptosing granulocytes and monocytes. The HLA-DRB1 shared epitope, which has been shown to specifically bind and present citrullinated self-peptides, is thought to predispose to this type of response. Targets for ACPA include fibrinogen, vimentin, α-enolase, and others, and these antibodies are thought to play a major role in disease pathogenesis, although the mechanism remains uncertain. The specific triggers of the ACPA response are also not firmly established, but evidence strongly suggests that inflammation at mucosal sites caused by environmental factors such as smoking, silicosis, periodontal disease, and the gut microbiome are responsible for initiating a limited ACPA response that expands in scope and consistency with clinical progression.

The next early arthritis phase is characterized by localization of the immune response and inflammation to joints. The resulting immune complexes and activated T cells lead to further stimulation of macrophages, synovial fibroblasts, endothelial cells, mast cells, and osteoclasts, and the eventual production of pro-inflammatory factors such as TNF, IL-1, IFN-γ, IL-17A, IL-23, chemokines, matrix metalloproteinases, osteopontin, and many others that contribute to synovitis, pannus formation, bone erosion, and cartilage destruction. This activity leads to a predominantly inflammatory and tissue-damaging phase largely mediated by activated fibroblast-like synoviocytes, which produce a wide array of pro-inflammatory mediators that promote recruitment and activation of circulating and resident immune cells.[200] It has also been suggested that the spread of arthritis to unaffected joints could, in fact, be mediated by transmigration of these activated fibroblast-like synovial cells.[201] The pathophysiology of the ACPA subset of RA provides an additional example of the collaboration of the innate and adaptive arms of the immune system in autoimmune disease, but it also has two unique features; first, the major autoantigen, citrullinated protein, is a neoantigen specifically targeted in this disease, and second, tissue damage is to a large extent mediated by fibroblast-like synoviocytes.

## GENETICS OF AUTOIMMUNE DISEASES

During the past two decades, substantial insight into the genetic landscape responsible for autoimmune disease susceptibility has emerged from both human and animal studies. This progress was greatly facilitated by the availability of genomic sequences, improved definition of genetic variations and haplotypes among human populations, consortia with collections of patients and control subjects in the thousands, and numerous major technical and analytical advances.[202,203] In particular, genetic studies have progressed from testing a few specific candidate polymorphisms to genome-wide family analyses of hundreds of cases, and even larger scale genome-wide association studies (GWAS) involving thousands,[204,205] making it possible to not only verify known genetic associations but also to capture common disease-predisposing variants with modest effects. Combined, these approaches have identified more than 100 candidate genes or loci in SLE and RA and in other rheumatologic diseases such as systemic sclerosis, Kawasaki's disease, Behçet's disease, spondylitis, and ANCA-associated vasculitis (reviewed in references 206-219; http://www.genome.gov/gwastudies).[206-219] These candidates span the gamut of innate and adaptive immune systems but also include some loci with genes of unknown immunologic function. For example, in SLE—one of the best defined at the genetic level of any rheumatic disease—candidate genes are involved in antigen presentation (HLA-DR3), B and T cell receptor signaling (*PTPN22*, *BANK1*, and *BLK*), CD4 T helper cell regulation (OX40L or *TNFSF4*), T cell–mediated regulation (*PDCD1*), cytokine signaling (*STAT4*), interferon and TLR7/9 signaling (*IRF5*, *TNFAIP3*, *IRAK1*, *IRF7*, and *TYK2*), Fc receptor function, one of which has been implicated in the transport of immune complexes containing nucleic acid to TLR7/9-containing endosomes (*FCGR2A*), neutrophil function (*ITGAM*), clearance of self-antigens (*C1Q*, *C2*, and *C4*), clearance of intracytoplasmic DNA (*TREX1*), and also several loci containing genes with no known connection to the immune system or lupus. Together, these candidates provide clues to specific pathways involved in SLE, which indeed has dovetailed well with genetic studies in mice.[10]

From GWAS and other studies, including those in animal models, several general conclusions can be made about genetic susceptibility in the more common autoimmune diseases. First, autoimmune diseases are associated with a large number of susceptibility genes that have been shown to have an impact on a wide range of immunologic, cellular, and end-organ functions in ways that enhance, modify, or even suppress relevant pathophysiologic processes.

Second, considerable genetic heterogeneity exists at both the individual and population levels regardless of whether the phenotype is relatively uniform, as in RA, or diverse, as in SLE. Thus, although a large number of predisposing genes exist, having only a subset of these genes is sufficient for disease development. Whether this heterogeneity is caused by variants affecting a few common pathways or numerous unique pathways remains unclear.

Third, the vast majority of candidate genes or loci have only modest effect sizes with most odds ratios less than 1.5, although in some diseases, notably SLE, a few rare variants such as *C1Q* deficiency associated with a greater than 90% incidence of SLE and *TREX1* mutations leading to chilblain lupus have been identified that are highly penetrant. Another salient finding derived from GWAS analysis is

that, for most autoimmune diseases, HLA alleles consistently have the highest or among the highest effect sizes. This finding accords well with the central role of antigen presentation and T cells in directing the adaptive immune response to specific antigens. Overall, however, for most candidate variations, defining the mechanism and proving a role in autoimmune disease will be hampered by their low effect sizes.

Fourth, some of the variant genes and loci are shared among autoimmune diseases, suggesting common underlying mechanisms.[220] Noteworthy examples are the association of *PTPN22* with a wide range of autoimmune diseases, including T1DM, RA, SLE, juvenile idiopathic arthritis (JIA), Graves' disease, systemic sclerosis, myasthenia gravis, generalized vitiligo, and granulomatosis with polyangiitis, but not MS,[221] *STAT4* with RA, SLE, systemic sclerosis, and Sjögren's syndrome.[222,223] This finding supports a role for such broadly predisposing genetic factors in the known occurrence of multiple different autoimmune diseases in some families.

Fifth, common single nucleotide polymorphism-defined variants account for only a portion of overall heritability in autoimmune diseases, that is, approximately 20% to 60%,[202,203,224] of which the HLA region typically accounts for a substantial part. Several reasons for the missing heritability have been suggested: (1) failed detection because of inadequate single-nucleotide polymorphism (SNP) coverage or the presence of disease-promoting non-SNP genomic variations such as copy number variants; (2) a large number of common variants with modest to marginal effects (odds ratio, <1.1 to 1.2) that are undetectable despite large study sizes given that the statistical power is reduced by both smaller effect size and lower variant frequency in the population; and (3) uncommon variants (1% to 5%) or rare disease-associated risk alleles (<1% frequency). Illustrating the hurdles that must be overcome to identify these rare variants on a genomewide scale, it was estimated that 25,000 cases plus a replication set would be required for a well-powered study.[225] Any of these possibilities present significant challenges to further defining genetic susceptibility. It should also be noted that most common SNP variants associated with diseases do not affect coding regions, making it difficult to determine if the SNP variant is the actual change associated with disease and to decipher its effects on gene function and autoimmunity, although new genomic approaches are being developed to tackle this challenge.

Finally, information gleaned from genetic studies to date has not been useful for identifying persons at risk, and it is thought that this situation will remain so because of the small effect sizes and relatively high frequency of known risk alleles combined with incomplete coverage of heritability.[203] Nevertheless, these data have helped define disease-relevant pathways and within that context have provided clues and support for potential therapeutic targets.

## GENDER AND AUTOIMMUNITY

A significant female gender bias in autoimmunity was identified early on and was considered an important clue to disease pathogenesis.[226] The strength of this predilection, however, varies among autoimmune disorders, with female prevalences in the 80% to 95% range for thyroiditis, SLE, Sjögren's syndrome, and anti-phospholipid syndrome; in the 60% to 75% range for RA, scleroderma, myasthenia gravis, and MS; and close to 50% for T1DM and autoimmune myocarditis.[227] Why some autoimmune diseases are affected more by gender than others is not known, but the lack of common or distinguishing characteristics in diseases with higher female predominance suggests the possibility of multiple mechanisms.

Indeed, to differing extents depending on the disease, both sex hormones and sex chromosomes have been implicated in this dichotomy.[228,229] In addition, fetal-maternal chimerism has been suggested as another factor, but this possibility remains controversial.[230] In terms of sex hormones, substantial evidence from in vitro, animal, and clinical studies supports a role for both female and male sex steroids in modifying the incidence and severity of autoimmunity. For example, in persons with SLE, both estrogens and prolactin have been shown to exacerbate disease. In animal studies, they promote loss of tolerance and expansion of B cell populations, which, for estrogens, was also shown to be associated with enhanced survival and greater expression of B cell lymphoma 2 (Bcl-2).[231] Importantly, studies of lupus-prone mice involving combinations of castration and hormone replacement convincingly demonstrated a disease-promoting effect of female hormones on spontaneous systemic autoimmunity.[232]

Less extensive evidence also supports a role for sex chromosomes in autoimmune disease susceptibility. Persons with Klinefelter's syndrome (XXY) have a higher than expected incidence of SLE, whereas there is contrastingly suggestive under-representation in Turner's syndrome (XO).[233,234] Furthermore, using genetic and gonad manipulation in mice that allowed direct comparison of the effects of one or two X chromosomes on autoimmunity, susceptibility to both EAE in SJL mice and TMPD-induced lupus was shown to be more severe in mice with XX.[235,236] Thus it appears that both hormonal and chromosomal influences play roles in female predilection to autoimmunity.

## MICROBIAL AND OTHER ENVIRONMENTAL TRIGGERS

Considerable evidence indicates that environmental factors can exert varying degrees of influence on the development of autoimmune diseases. A clear causal effect has been documented for a few disorders, whereas the low concordance rate (20% to 50%) among monozygotic twins in common autoimmune diseases supports the presence of a significant environmental component. Nevertheless, the specific environmental factors and the extent to which they contribute to disease induction and exacerbation remain largely unknown for most autoimmune disorders. The reasons for this lack of knowledge are likely manifold and, depending on the disease, may include unsuspected or unknown environmental culprits, multiple independent factors, additive factors contributing to cumulatively small portions of the overall environmental effect, a highly variable or prolonged interval between exposure and disease onset, and a low incidence of autoimmune disease after exposure. Moreover, another general impediment is the difficulty of proving causation with epidemiologic data. Because of these difficulties, animal studies have been invaluable in allowing controlled

experimentation, and much of what we understand mechanistically has come through this approach.

Despite the aforementioned limitations, a broad range of environmental factors have been implicated, albeit with varying levels of confidence.[237] Notably, the most prominent are infection and exposure to microbial products, which epidemiologic and animal models suggest can either enhance or inhibit autoimmunity depending on the type of exposure and disease.[238,239] Rheumatologic examples include Reiter's syndrome after certain enteric infections, chronic Lyme arthritis resulting from *Borrelia burgdorferi*, and the association of oral *Porphyromonas gingivalis* that expresses a peptidylarginine deiminase that can citrullinate proteins with RA. Several mechanisms by which microbes are postulated to induce or exacerbate autoimmunity include (1) molecular mimicry,[183] (2) bystander activation of autoreactive T cells by pathogen-activated antigen-presenting cells,[240] (3) inflammation of the target tissue and the release of immunologically hidden self-antigens,[241] and (4) production of disease-promoting cytokines, such as IFN-α.[49] Inhibition of autoimmune diseases by pathogens was initially suggested by epidemiologic evidence in persons with T1DM and MS consistent with the "hygiene hypothesis"—that is, a lower incidence of infection is responsible for an increasing incidence of allergic disease in Western countries.[242] This concept has since been supported by additional epidemiologic and experimental data, although the microbial pathogens, type of exposure, and mechanisms remain uncertain. Studies of T1DM-prone NOD mice, which worsen in clean conditions and improve with exposure to microbial products, showed that alterations in gut microbiota, which can interact with and modulate the host immune and inflammatory apparatus, could account for a significant portion of the environmental effects and even influenced the female gender bias.[243-246] Many of these mechanisms do not require a specific pathogen but can be mediated by a wide spectrum of organisms. Finally, in some animal models, autoimmune disease develops under germ-free conditions, thereby excluding an absolute requirement for microbial environment or infection. In this case, one would infer that the trigger is provided by self, most likely cell damage–derived products. Examples include T1DM in NOD mice and BB rats, APECED in *Aire*-deficient mice, IPEX in the presence of Foxp3 deficiency, and lupus in MRL-lpr mice.[247-251] Interestingly, however, in MRL-*lpr* mice, the addition of a filtered diet containing fewer pathogen-associated molecular patterns (PAMPs) reduces disease severity. This finding suggests that microbial products at least partially affect disease susceptibility in this model and points to the difficulty of completely excluding a role for microbial organisms.

In terms of the other nonmicrobial environmental factors, some of the general types include (1) drugs such as procainamide, gold salts, and interferons that typically cause mild autoimmunity that resolves after discontinuation; (2) trauma, exemplified by sympathetic ophthalmia caused by penetrating injury to the globe; and (3) diverse environmental agents such as adulterated oil (which causes toxic oil syndrome), ultraviolet radiation (which exacerbates systemic autoimmunity), iodine (which causes autoimmune thyroiditis), silica (which causes RA, SLE, and systemic sclerosis), and tobacco smoke (which causes $ACPA^+$ $HLA\text{-}DR4^+$ RA).[164,237]

## CONCLUSION

Since 1904, when Donath and Landsteiner reported the first evidence of self-reactivity in paroxysmal hemoglobinuria,[252] the field of autoimmunity has progressed tremendously at both the clinical and basic science levels. Notably, recent progress since the last edition of this book has made it possible to define with greater detail and confidence the interrelationships between genetic susceptibility, environment, and pathophysiology, and indeed, novel pathways have been identified that link cause with immunopathology. Advances have continued to broaden appreciation for the central role of the innate response in initiating autoimmunity and in determining the type of adaptive autoimmune response and type of autoimmune disease. Large genome-wide association projects have progressed to identifying and characterizing causative variants. Advances in the understanding of disease pathogenesis primarily in more common rheumatologic diseases have further solidified and extended existing frameworks from which researchers can build to identify critical pathways and molecules. Of importance to patient care has been the successful bench-to-bedside translation approach that has resulted in the continued advancement of therapeutic targeting of immune-related molecules to the clinic. Despite this progress, many important facets of autoimmunity are unresolved, and patient care remains suboptimal. Importantly, the highly sought-after objective of specifically re-establishing tolerance in patients has remained elusive despite considerable effort,[253] and current, more broadly immunosuppressing therapies are only partially effective and are associated with infection and cancer risks. Accordingly, there continues to be a critical need to investigate the basic processes involved in autoimmune diseases and to develop new and more effective clinical management.

CHAPTER 20

# Metabolic Regulation of Immunity

Ruoning Wang • Tingting Wang • Stephen Tait

**KEY POINTS**

- Immune signaling drives metabolic reprogramming in both innate and adaptive immune cells.
- The metabolic shift renders immune cells highly dependent on certain metabolic pathways.
- Mitochondria serve as signaling hubs for directing innate and adaptive immune responses.
- The availability of extra-cellular metabolites mediates the intercellular metabolic cross-talk that affects the immune response.

## OVERVIEW

The evolution of vertebrate immunity has culminated in an effective and complex chain reaction, which is composed of a rapid activation of specialized innate immune cells—largely neutrophils, macrophages, and dendritic cells (DCs)—followed by the proliferative burst and functional polarization of adaptive immune cells, that is, B and T cells. Because the invading pathogens of vertebrates often rapidly reproduce and spread in their host, an effective host-mediated immune response must be fast and energy intensive. As we discuss in this chapter, an immune signaling–driven metabolic reprogramming in both innate and adaptive immune cells may be essential for their activation, proliferation, and polarization and for the subsequent functional events elicited by these cells (Figure 20-1).

## METABOLIC REWIRING IN INNATE IMMUNITY

### Macrophage Metabolism

Macrophages, together with DCs, are considered first-line effectors of innate immunity. Based on their specific functional activities after pathogen or cytokine stimulation, macrophages can be largely defined as two different subtypes: the classically activated macrophage subset (M1) and the alternatively activated macrophage phenotype (M2). The classic activation of macrophages is often induced by a combination of bacterial product lipopolysaccharide (LPS) and cytokines such as interferon-γ (IFN-γ), whereas the polarization of macrophages via the alternative activation program is triggered by exposure to the cytokine interleukin (IL)-4 or IL-13.[1] M1 macrophages produce nitric oxide (NO), a product of inducible nitric oxide synthase (iNOS)–mediated breakdown of arginine, reactive oxygen species (ROS), and pro-inflammatory cytokines, including tumor necrosis factor (TNF), IL-1β, IL-6, and IL-12, thus mounting a rapid, effective response against highly proliferative intra-cellular pathogens. In contrast, M2 phenotype macrophages produce high levels of IL-10 and IL-1 receptor antagonist (IL-1ra), meanwhile shifting arginine catabolism from iNOS-mediated production of NO to an arginase I (Arg I)–mediated breakdown of arginine into urea and ornithine, thus functioning in anti-parasitic responses, promoting tissue healing, and, in general, dampening inflammation.[2-4] Therefore, M1 macrophages promote inflammation, whereas M2 macrophages suppress inflammation and promote tissue repair. In addition to the differential engagement of an iNOS-dependent or Arg I–dependent arginine catabolic program, the differences of M1 and M2 macrophages are also reflected in their other metabolic profiles. Whereas the inflammatory M1 macrophages predominantly engage glycolysis and the pentose phosphate shunt (PPP), the anti-inflammatory M2 macrophages actively engage lipid oxidation.[1,5]

Heightened glycolysis is required for adenosine triphosphate (ATP) generation in M1 macrophages and also provides many glycolytic intermediate metabolites, which are direct precursors for lipid and amino acid biosynthesis. Whereas newly synthesized lipids are involved in the dramatic intra-cellular membrane reorganization after pathogen invasion, both lipids and amino acids are required for the production and secretion of pro-inflammatory cytokines.[6-9] Meanwhile, the PPP pathway provides nicotinamide adenine dinucleotide phosphate (NADPH), which functions in maintaining reduced glutathione and limiting oxidative stress in M1 macrophages.[10-12] Enhanced glycolysis and PPP in M1 macrophages also results in glucose depletion and an acidified microenvironment, resulting in a hostile environment that may suppress pathogen proliferation.[13] It has been demonstrated that the metabolic reprogramming in M1 macrophages is tightly coordinated by transcriptional and post-translational regulation of metabolic enzymes. LPS stimulation in M1 macrophages leads to a transcriptional induction of glycolytic enzymes such as phosphoglycerate kinase (PGK), the glucose transporter-1 (GLUT-1), and ubiquitous 6-phosphofructo-2-kinase/fructose-2, 6-bisphosphatase (uPFK2) to promote glycolysis, meanwhile suppressing the expression of mitochondrial enzymes.[14,15] In addition, LPS stimulation results in a robust NO production, which not only plays an indispensable role in destroying invading microorganisms but also results in a suppression of mitochondrial oxidative phosphorylation, likely via S-nitrosylation of mitochondrial metabolic

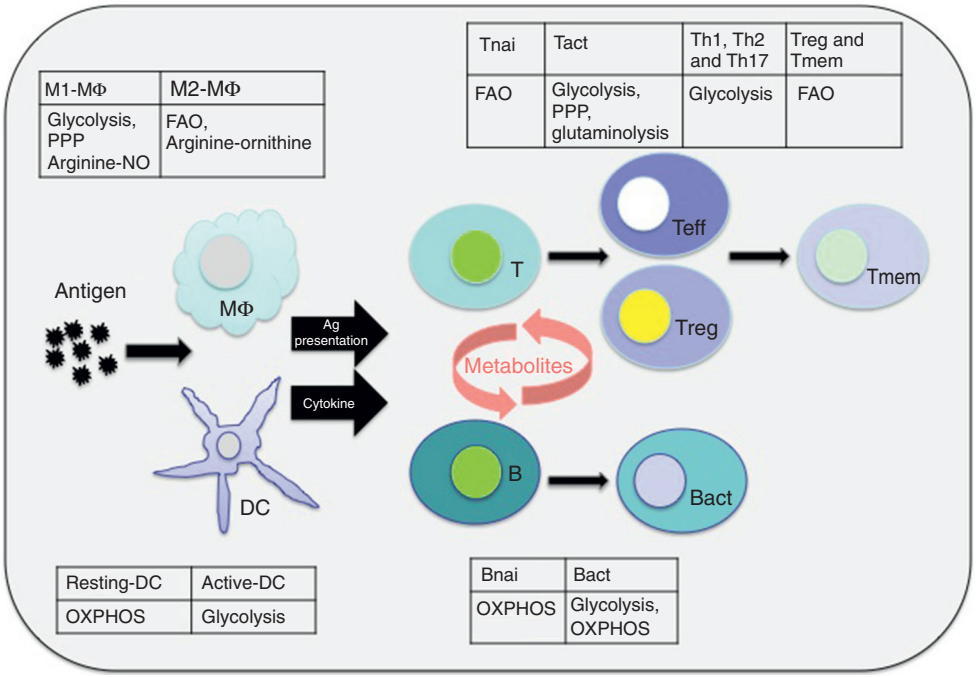

**Figure 20-1** Metabolic reprogramming and interplay in immunity. Resting dendritic cells (DCs) mainly rely on the mitochondrial oxidative phosphorylation (OXPHOS) metabolic pathway, whereas active DCs rapidly switch from OXPHOS to glycolysis after activation. M1 macrophages (MΦ) engage glycolysis, pentose phosphate shunt (PPP), and inducible nitric oxide synthase (iNOS)–mediated arginine catabolism that generates nitric oxide (NO), whereas M2 MΦ predominantly rely on fatty acid oxidation (FAO) and convert arginine to ornithine and urea. Upon antigen and cytokine stimulation, naïve T (Tnai) cells become active and undergo a metabolic reprogramming from FAO to glycolysis, PPP, and glutaminolysis. Active T (Tact) cells then differentiate into effector T (Teff) cells with heightened glycolysis, as well as regulatory T (Treg) and memory T (Tmem) cells that depend on FAO. Unlike T cells, naïve B (Bnai) cells rely on OXPHOS, whereas active B (Bact) cells display a balanced increase in glycolysis and OXPHOS. Beyond this, the different immune populations may interplay with each other through competing nutrients or formation of metabolic symbiosis.

enzymes.[16,17] The transcriptional factor hypoxia-inducible factor-1α (HIF-1α) has also been implicated in the regulation of glycolysis, in addition to its role in promoting the transcription of proangiogenic factors and pro-inflammatory cytokines in macrophages.[15,18] On the other hand, a recent study found that a rapid downregulation of carbohydrate kinase–like protein (CARKL) after LPS stimulation is required for shunting glucose catabolism into the oxidative arm of the PPP pathway in M1 macrophages. It was suggested that CARKL possesses the same catalytic activity as the sedoheptulose kinase, which promotes metabolic flux through a nonoxidative arm and consequentially reduces metabolic flux through the oxidative arm of the PPP. The nonoxidative arm of the PPP is designed to generate ribose-5-phosphate (R5P), whereas the oxidative arm of the PPP produces NADPH, thus modulating redox balance. Intriguingly, M2 macrophages display higher CARKL expression than do M1 macrophages, implicating CARKL as a rheostat for coordinating macrophage metabolic routes and functional polarizations.[19] Beyond this, IL-4, an M2 macrophage stimulator, dramatically induces the signal transducer and activator of transcription 6 (STAT6), which promotes the transcription of Arg1, thus shifting arginine catabolism from iNOS-mediated production of NO to the production of urea and ornithine.[20] STAT6 also cooperates with peroxisome proliferator-activated receptor γ (PPARγ)-coactivator-1β (PGC-1β) to induce the expression of genes involved in fatty acid oxidation (FAO) and mitochondrial biogenesis in M2 macrophages.[21]

## Dendritic Cell Metabolism

DCs, which are key players in immunity and tolerance, play a crucial role in driving T cell activation and differentiation via antigen presentation and production of cytokines. DCs can be divided into several subsets, including conventional DCs (cDCs), inflammatory DCs (infDCs), and plasmacytoid DCs (pDCs).[22-24] Resting DCs, which are largely immature and poorly immunogenic, mainly rely on the mitochondrial oxidative phosphorylation (OXPHOS) metabolic pathway. Upon the stimulation of pathogen-derived toll-like receptor (TLR) ligands, DCs become active and immunogenic and undergo a rapid metabolic switch from OXPHOS to glycolysis to fulfill their bioenergetic needs.[25-27] In addition, many intermediate metabolites of the glycolytic pathway provide a carbon source for amino acid biosynthesis and de novo fatty acid synthesis, the latter of which is required for the synthesis of endoplasmic reticulum (ER) and Golgi membranes to promote the synthesis, transportation, and secretion of proteins associated with DC activation and maturation.[25,28] Mechanistically, the engagement of TLR ligands leads to the activation of phosphatidylinositol 3-kinase (PI3K)/protein kinase B (Akt) pathway, which may directly promote GLUT membrane translocation and enhance glucose uptake in DCs.[25,29,30] As an essential downstream signaling node of the PI3K/Akt signaling pathway, the mammalian target of rapamycin (mTOR) has also been implicated in modulating metabolic programs in both cDCs and infDCs.[25,29,31] The activation of

mTOR results in the expression and stabilization of transcription factor HIF-1α, which regulates the expression of genes involved in glycolysis. The transcription factor sterol-regulatory element binding protein (SREBP) is another downstream target of mTOR and is responsible for controlling genes relevant in lipid synthesis.[32-34] Similar to M1 macrophages, an iNOS-derived NO may play a critical role in suppressing mitochondrial OXPHOS, thus promoting the metabolic shift from mitochondrial-dependent metabolism to glycolysis in DCs. Other reports also suggested that the autocrine production of type I IFN is required for the metabolic switch in cDCs.[26,27,35] Whereas the engagement of glycolysis is required for TLR-induced DC activation and immunogenicity, mitochondrial OXPHOS is likely involved in DC-mediated immune tolerance. Consistent with findings in other immune cells, recent studies indicated that adenosine monophosphate (AMP)–activated protein kinase (AMPK) and peroxisome proliferator-activated receptor-γ coactivator (PGC)-1α form a signaling axis to coordinately regulate mitochondrial biogenesis, OXPHOS, and other catabolic metabolisms in DCs, thus favoring the acquisition of tolerogenic DCs.[25,36-39]

## METABOLIC REWIRING IN ADAPTIVE IMMUNITY

### T Cell Metabolism

As an essential component of adaptive immunity, T cells can recognize foreign antigen and rapidly transit from a quiescent to an active state that is concomitant with cell growth (increase of cell size) and proliferation. Subsequently, activated and proliferating T cells can differentiate into various functional subsets, which are determined by the nature of antigen stimulation and the surrounding cytokine milieu. Subsequent to the peak of T cell expansion and antigen clearance, the vast majority of T cells will die by programmed cell death (apoptosis) during a phase of contraction. The remaining population returns to a quiescent state and gives rise to the memory subset, which responds more quickly and effectively upon encountering with the same pathogen. To fulfill their bioenergetic and biosynthetic demands coupled with various functional stages, T cells actively engage distinct signaling pathways and transcriptional modulators to alter their metabolic programs accordingly.

#### T Cell Activation

Upon the engagement of antigen and co-stimulatory molecules, resting T cells undergo a rapid growth and proliferation process. Concomitant with this process, and as a result of activation signaling, T cells reprogram their metabolic profile, shifting from FAO to robust aerobic glycolysis, PPP, and glutaminolysis. Naïve T cells rely on OXPHOS, generating energy to meet the basic needs for cell function and survival. Heightened aerobic glycolysis and glutaminolysis in activated T cells not only support ATP generation but also provide biosynthetic intermediates as building blocks of amino acids, nucleotides, and lipids to fulfill the biosynthetic demands of rapid cell growth and proliferation. In addition, glutaminolysis and glycolysis in active T cells provide carbon and nitrogen for other growth and proliferation-associated biosynthetic pathways, such as hexosamine and polyamine biosynthesis. Shunting of glucose into the PPP pathway results in the production of R5P and NADPH. Whereas R5P is a precursor for ribonucleotide biosynthesis, NADPH determines cellular redox balance and coordinates to FFA and cholesterol biosynthesis through the provision of reducing equivalents.[40-43]

The rewiring of metabolic pathways upon T cell activation is coordinately regulated by several signaling pathways, including mitogen-activated protein kinase (MAPK)/extra-cellular signal-regulated kinase (ERK) and PI3K/Akt/mTOR cascades.[40,44] The activation of Akt signaling promotes the expression and cell surface trafficking of GLUT-1 to the cell surface, facilitating glucose uptake.[45,46] On the other hand, ERK signaling promotes glutamine uptake via modulation of sodium-dependent neutral amino acid transporter-2 (SNAT2) expression and cell membrane trafficking.[47] Beyond the regulation of glucose and glutamine uptake, T cell activation signaling drives a global metabolo-transcriptome, including most of the key metabolic enzymes involved in the aforementioned catabolic and biosynthetic pathways. Interrogation of the promoters of these genes and subsequent genetic modulation of candidate transcriptional factors in T cells revealed that the proto-oncogene Myc is required in T cell activation–driven glucose and glutamine catabolism.[40,44] Meanwhile, metabolic genes involved in lipid metabolism and de novo cholesterol biosynthesis and transport are under the dynamic regulation of transcriptional factors, nuclear receptor liver X receptor (LXR), and the orphan steroid receptor estrogen receptor-related α (ERRα).[48-50]

#### T Cell Differentiation

After a rapid initial growth phase, T cells enter a proliferation phase and subsequently differentiate into various phenotypic and functional subtypes. In response to the distinct antigen challenge and extra-cellular cytokine signal, activated $CD4^+$ T cells differentiate into immune suppressive regulatory T cells (Tregs) or inflammatory T effector cells, such as T helper (Th)1, Th2, and Th17 (see Chapter 12). Th1 cells mediate responses to intra-cellular pathogens. Th2 cells control responses to extra-cellular bacteria and helminthes. Th17 cells are important in anti-fungal defense and inflammation.[51-53] Despite their distinct functions in immunity, Th1, Th2, and Th17 cells all sustain heightened glycolysis, whereas Treg cells show decreased glycolysis.[49,54] Although the regulatory mechanism of elevated glycolysis in Th1 and Th2 cells remains unclear, HIF-1α is indispensable for driving Th17 differentiation and sustaining elevated glycolysis during Th17 differentiation.[49,54] Consistent with the crucial role of mTOR in regulating T effector development,[55,56] the expression of HIF-1α is dependent on the function of mTOR during Th17 differentiation. Whereas heightened glycolysis is necessary for Th17 differentiation and function,[54] HIF-1α appears to also directly regulate Th17 differentiation, at least in part through direct transcriptional activation of the Th17 master transcription factor, RAR-related orphan receptor γ (RORγt), thereby enhancing Th17 differentiation.[57] On the other hand, HIF-1α suppresses Treg differentiation, partially by antagonizing

forkhead box protein 3 (Foxp3), a master transcriptional factor for Treg differentiation.[57] Treg cells act as immunologic suppressors by dampening T cell activation and inflammatory response. In contrast to other Th cells that actively engage glycolytic programs, Treg cells exhibit a reliance on mitochondrial-dependent oxidation of lipids for energy production.[49] Consistent with this mechanism, exogenous fatty acid supplementation inhibits Th1, Th2, and Th17 differentiation while modestly enhancing Treg differentiation.[49] In addition, butyrate, a commensal microbe-derived short-chain fatty acid, preferentially induces Treg differentiation. However, this effect may be due to the inhibition of histone deacetylase activity by butyrate.[58,59] Similar to CD4 T cells, activated CD8 T cells also switch from FAO to aerobic glycolysis and sustain elevated glycolysis and anabolic metabolism for CD8 T cell growth and differentiation into cytotoxic T cells.[60] After the peak of cell proliferation and differentiation, the metabolic profile of T cells shifts from glycolysis back to FAO, partially as a result of decreased mTOR signaling.[61-63] Therefore, the metabolic switch is postulated to be required for the generation of memory CD8 T cells. Taken together, T cell activation and differentiation are tightly coupled with metabolic reprogramming.

### B Cell Metabolism

B cells, which produce antibodies against pathogens, represent another critical component in adaptive immunity. Whereas T cells rapidly engage robust glycolytic programs upon antigen stimulation, B cells display a balanced increase in aerobic glycolysis and mitochondrial glucose oxidation after the engagement of the B cell antigen receptor (BCR) or LPS-mediated activation of TLR signaling. This balanced increase is likely because of a proportionally upregulated GLUT and mitochondrial mass.[64,65] Accumulating evidence has indicated that the engagement of glycolysis is tightly regulated by intra-cellular signal transduction pathways after B cell activation and is required for B cell proliferation and antibody production. It has been reported that the PI3K/Akt pathway is indispensable for glucose uptake and utilization, because the activation of Akt is sufficient to increase glucose metabolism in B cells.[66-68] Differentiation of B cells into immunoglobulin-secreting plasma cells is accompanied by the expansion of the intra-cellular membrane network, where immunoglobulin is produced and secreted. Such endomembrane network expansion requires the engagement of de novo lipogenesis. The PI3K/Akt signaling pathway is required to activate ATP-citrate lyase (ACLY), a key enzyme that channels the carbon of glucose to lipids through conversion of citrate to cytosolic acetyl-coenzyme A (CoA).[69,70] In addition, IL-4 has been shown to promote B cell survival by regulating glucose metabolism via the Janus kinase 1/3 (JAK1/3)-STAT6 signaling pathway.[65] Poly (adenosine diphosphate [ADP]-ribose) polymerase 14 (PARP14), an ADP ribosyltransferase, may represent another important downstream effector of IL-4 signaling, interplaying with STAT6 and modulating glycolysis in B cells.[71] Although HIF-1α is required for regulating glycolysis in B cell development in bone marrow,[72] it is dispensable for driving glycolysis in active B cells. Rather, an Myc-dependent upregulation of GLUT1 and likely other glycolytic genes are required for engaging glycolysis after B cell activation.[64]

## MITOCHONDRIA AND IMMUNITY

It has recently become apparent that mitochondria play multiple, key roles in immunity. In addition to their critical biosynthetic function, mitochondria are intimately involved in immunity, where they serve as both initiators and transducers of various signaling cascades. Immunity can be divided into innate, pre-existing, or acquired, such that it develops after pathogenic challenge. Direct signaling roles for mitochondria have been best described in the context of innate immunity. Innate immune cells including macrophages or DCs detect infectious pathogens or damaged cells through pathogen recognition receptors (PRRs).[73] PRRs recognize conserved molecular patterns shared by microorganisms (pathogen-associated molecular patterns [PAMPs]) and damaged cells (damage-associated molecular patterns [DAMPs]). PRR pathway activation leads to the production of various pro-inflammatory and anti-microbial cytokines, including type I IFNs and IL-1. Through their action, these cytokines simultaneously create an anti-microbial environment and stimulate the development of adaptive immunity against the invading pathogen. As we will now discuss, mitochondria regulate multiple aspects of innate immune signaling, where they serve as both initiators and effectors of PRR signaling. We will review the roles of mitochondria in transducing signals elicited by three separate PRR families: retinoic acid inducible gene (RIG-I)–like receptors (RLRs), TLRs, and nuclear oligomerization domain (NOD)–like receptors (NLRs).

### Mitochondria and NOD-Like Receptor Signaling

Many PAMPs and DAMPs activate cytoplasmic complexes called *inflammasomes*.[74] After activation, inflammasomes activate the protease caspase-1, which, in turn, cleaves various pro-inflammatory cytokines, leading to their maturation and cellular release. The best-described cytoplasmic NLR is NLRP3. NLRP3 inflammasomes recruit and activate caspase-1 via the adaptor protein ASC. Various roles for mitochondria in promoting NLRP3-activation have been proposed; for example, recent data implicate the mitochondrial protein MAVS in NLRP3 inflammasome activation. MAVS is a key player in anti-viral immunity engaged by RLR, however, it has also recently been shown to interact with NLRP3, leading to NLRP3 mitochondrial recruitment, thus promoting NLRP3-inflammasome assembly and activation.[75,76] Nevertheless, although it facilitates NLRP3 activation, MAVS is not essential because MAVS-deficient cells retain NRLP3 activity.[77] In a separate study, microtubule-dependent transport of mitochondria to the endoplasmic reticulum (ER) promotes NLRP3-inflammasome activation by bringing together the key inflammasome-adaptor molecule, ASC (present on mitochondria) with NLRP3 (present on the ER).[78] Supporting this model, previous work has shown that active NLRP3 inflammasomes reside at mitochondrial-ER contacts.[79] Interestingly, mitochondrial transport depends upon acetylated tubulin, suggesting that mitochondrial metabolism (producing the acetyl-CoA

required for acetylation) may also regulate inflammasome activity. Why would recruitment of NLRP3 to the mitochondria, either via MAVS or ASC, facilitate inflammasome activation? Potentially, mitochondria simply act as a physical scaffold that promotes inflammasome assembly. Alternatively, mitochondria may actively participate in inflammasome activation. Along these lines, different studies have shown that mitochondrial ROS promote NLRP3 activity.[79,80] Various DAMPs and PAMPs trigger mitochondrial ROS, and blocking ROS production (using ROS scavengers) can effectively block NLRP3-inflammasome activation.[79] It is not clear how ROS promotes NLRP3-inflammasome activation; similarly, it is not known how such diverse stimuli give rise to ROS. Besides mitochondrial ROS, other mitochondrial molecules such as cardiolipin and mitochondrial DNA (mtDNA) have been proposed to facilitate NLRP3 activation.[80,81] As we have discussed, there are numerous means by which mitochondria may promote NLRP3 activity; nevertheless, these means remain controversial. Whether mitochondria are required for NLRP3-activation is a question that may be readily addressed using a recently described method to generate mitochondria-deficient cells.[82]

## Mitochondria and RIG-I-Like Signaling

RLRs are the primary means by which cytoplasmic viral double-stranded RNA (dsRNA) is detected. RLR signaling ultimately leads to the production of type-1 IFN and pro-inflammatory cytokines, thereby inhibiting viral replication and promoting acquired immunity. In simplistic terms, binding of viral dsRNA to RIG-I or melanoma differentiation–associated protein 5 (MDA5) triggers its binding to MAVS, which is located on the mitochondrial outer membrane. MAVS then undergoes oligomerization, permitting it to bind adaptor molecules TRAF3 and TRAF6; these molecules subsequently activate interferon regulatory factor (IRF) and nuclear factor-κB (NF-κB) transcription factors, leading to anti-viral interferon and pro-inflammatory cytokine production.[83] MAVS is a resident mitochondrial outer membrane protein, and various reports highlight an active role for mitochondrial dynamics in regulating RLR, MAVS-dependent signaling. Mitochondria are constantly undergoing rounds of fission and fusion with one another, thereby promoting mitochondrial homeostasis. Interestingly, RLR signaling via MAVS requires mitochondrial fusion because cells deficient in mitofusins (MFN) 1 and 2 or optic atrophy type 1 (OPA-1)—all proteins that are required for mitochondrial fusion—are defective in MAVS signaling.[84,85] Similarly, Ψ disruption of mitochondrial membrane potential ($\Psi_m$), leading to mitochondrial fragmentation, also inhibits MAVS-dependent signaling.[86] It remains unclear why an intact mitochondrial network supports MAVS signaling, although in research that potentially addresses this question, MAVS activation has been shown to occur in a prion-like manner, whereby one activated MAVS molecule activates another.[87,88] Potentially, a continuous, fused mitochondrial network facilitates sufficient MAVS oligomerization to support downstream signaling. It is important to note that because of its pleiotropic effects, disruption of mitochondrial membrane potential may affect MAVS signaling by additional means beyond disrupting mitochondrial fusion. Similarly, MFN2 has additional fusion-independent functions, for example, in mitochondrial-ER tethering.[89]

## Mitochondria and Toll-Like Receptor Signaling

TLRs are localized at both the plasma membrane and various intra-cellular organelles that include lysosomes and endosomes. This nine-membered family responds to various PAMPs derived from bacteria, viruses, fungi, and parasites, transducing signals that ultimately lead to the production of pro-inflammatory cytokines.

A key facet of innate immunity is the destruction of intra-cellular bacteria. After phagocytosis, ROS are induced, leading to the killing of intra-cellular bacteria. Most ROS produced during this process originate from NADPH oxidases; however, recent evidence also demonstrates an important role for TLR-driven mitochondrial ROS.[90] Triggering of specific TLRs triggers translocation of the TLR-adaptor molecule, TRAF6, to the mitochondria. At the mitochondria, TRAF6 ubiquitylates evolutionarily conserved signaling intermediate in toll pathways (ECSIT), a protein implicated in complex I assembly.[91] Through means that are unclear, ubiquitinated ECSIT triggers mitochondrial ROS production and pathogen clearance. Beyond these effects, TLR engagement has been shown to effect mitochondrial metabolism in other ways. For example, LPS increases the mitochondrial Krebs cycle intermediate metabolite, succinate, that induces pro-inflammatory IL-1β expression.[18]

## Mitochondria as a Source of Danger Signals

Thus far we have discussed mitochondria as key signaling platforms in a variety of innate signaling cascades. Likely stemming from their bacterial ancestry, mitochondria also represent a rich source of DAMPs. Chief among these is mtDNA, which contains hypomethylated cytosine-phosphatidyl-guanine (CpG) motifs similar to bacterial DNA. In line with a pro-inflammatory function, direct injection of mtDNA, but not nuclear DNA, leads to inflammation.[92] Moreover, systemic release of mtDNA after trauma has been proposed to underlie systemic inflammatory response syndrome, a form of septic shock.[93] Besides mtDNA, other mitochondrial molecules may also serve as DAMPs. Again, similar to bacteria, mitochondria also use *N*-formyl-methionine as the translation initiating residue. Both can stimulate cytokine production after binding of formyl peptide receptors (FPRs).[93]

# METABOLIC INTERPLAY IN THE IMMUNE MICROENVIRONMENT

Aerobic glycolysis, glutaminolysis, and other amino acid catabolism are dominant metabolic routes for many pathogen-encountered immune cells. Thus, those heightened catabolic pathways cause local depletion of nutrients (e.g., glucose and glutamine) and local accumulation of metabolic end- or by-products (e.g., lactate, proton, and NO) in infection and inflammatory sites. The similarity of metabolic programs among some immune cells may lead to a potential metabolic antagonism for limited nutrient

sources. On the contrary, some immune cells may preferentially utilize metabolic products of others to form a potential metabolic symbiosis (see Figure 20-1).

### Metabolic Antagonism in Immunity

The metabolic competition among active T cells, B cells, and DCs may lead to a rapid, albeit transient, nutrient depletion after immune activation. The restriction of glucose and glutamine results in metabolic stress and, consequentially, elicits signaling responses through AMPK and mTOR to modulate immune responses.[41,56,94] In addition, the depletion of extra-cellular tryptophan or arginine by DCs and macrophages that express amino acid catabolic enzymes such as indolamine 2,3-dioxygenase (IDO), tryptophan-2,3-dioxygenase (TDO), and arginase I (Arg I) often results in the depletion of local amino acids, and consequentially the activation of the protein kinase GCN2 (general control nonrepressed 2) in T cells.[95-98] Therefore Th17 differentiation is suppressed, whereas Treg development and T cell anergy are enhanced.[95,99] Furthermore, the secreted metabolic products may dramatically change the local metabolic environment and may form additional metabolic antagonism to shape immune cell functions. The lactate and carbon dioxide produced from glycolysis and glutaminolysis lead to microenvironment acidification, which suppresses T cell proliferation, impairs NK cell and T cell cytokine production, and has a profound impact on monocyte differentiation.[100-103] Beyond this, the cross-membrane transport of sodium ions is intimately coupled with proton and amino acids transport and has a profound impact on immune function.[104,105] Recent studies showed that high-sodium chloride conditions induce the development of pathogenic Th17 cells with elevated release of pro-inflammatory cytokines (granulocyte-macrophage colony-stimulating factor [GM-CSF], TNF, and IL-2) and thus promote tissue inflammation.[106,107] Also, iNOS-mediated breakdown of arginine into NO affects both the intra-cellular and extra-cellular redox balance and consequentially elicits immune modulatory effects.[108,109]

### Metabolic Symbiosis in Immunity

Lactate has been shown to mediate a form of metabolic symbiosis in muscle, brain, and certain tumors.[110-112] Although it has not been demonstrated, the preference of mitochondrial-dependent oxidative metabolism of Treg cells indicate the possibility that Treg cells may utilize lactate and form a metabolic symbiosis with other lactate-producing immune cells. The concentration of lactate in vertebrate plasma ranges from 1 to 30 mM under physiologic and pathologic conditions.[113] Early studies have shown that lactate enhances Treg differentiation through the stimulation of IL-2 production and, in another case, promotes the development of myeloid-derived suppressor cells (MDSCs).[100,114,115] In addition, lactate and acidic environments have a profound impact on tumor-associated macrophages (TAMs), promoting tumor angiogenesis.[103,116-118] Beyond this, the breakdown of tryptophan to kynurenine and potentially other intermediate metabolites in antigen-presenting cells results in the accumulation of nature ligands of aryl hydrocarbon receptor (AHR) in the local microenvironment, which plays a broad role in modulating immunity.[119,120] As such, extra-cellular accumulation of kynurenine elicits an AHR-mediated response to reciprocally enhance function of Tregs and suppress the function of effector T (Teff) cells and immunogenicity of DCs.[121-123] Thus kynurenine may mediate another form of metabolic symbiosis in immunity.

## CONCLUSION

In this chapter, we illustrate the relevant metabolic aspects of immune cells that have recently been revealed. In addition, we discuss the potential regulatory mechanism of metabolic reprogramming and the consequences of metabolic intervention on specific metabolic pathways in the immune response. The metabolic shift in immune cells during the transition between rest and activation is often associated with dramatically increased bioenergetic and biosynthetic demands. This may also lead active immune cells to become "addicted" to certain metabolic pathways in ways that resting cells are not. Thus, the modulation of such addiction, in terms of the biologic effects of enhancement or inhibition of specific pathways in immune cells, may offer novel therapeutic regimes to improve immunologic unresponsiveness or to suppress excessive immune responses, respectively. In addition to other known soluble protein factors, such as cytokines and chemokines, the availability of specific metabolites in the infection/inflammation microenvironment may be part of a pro-inflammatory or anti-inflammatory signaling circuit that affects the immune response. This is independent of their roles of bioenergetic fuels and may represent a general feature of the intercellular metabolic cross-talk mediated by metabolites. The revived interest in cell metabolism has revealed many fundamental biological insights and will likely generate new therapeutic strategies for immunologic diseases in the near future.

CHAPTER 21

# Genetics of Rheumatic Diseases

Stephen Eyre • Peter Gregersen • Anne Barton

**KEY POINTS**

- In recent years, major advances in our knowledge of the genetic basis for musculoskeletal diseases have been achieved.
- In many cases the causal gene and causal variants of disease have not yet been defined, although a locus of association has been identified.
- Exploiting the genetic data that are available is providing insights into the key risk pathways and primary cell types responsible for disease and may highlight targets for novel drug development.
- Translating genetic testing into the clinical setting is still premature; more work and possible integration with other data is required to identify signatures of drug response and prognosis.

Many of the musculoskeletal diseases seen by rheumatologists are thought to arise as a result of an environmental insult that triggers disease in a genetically susceptible person. As such, these diseases are known as complex diseases because both genes and the environment contribute to the risk of disease development. Genetic risk factors are easier to study than environmental risk factors because genetic variants are present from conception (and therefore must have been present before disease onset and could be causal), are stable throughout life, and are easily measured. In contrast, information about environmental risk factors is often collected after disease has developed, and the exposure could have occurred many years before disease onset, thereby introducing recall bias, or the exposure is measured after initial symptom onset, making it difficult to separate cause from effect. Furthermore, environmental risk factors often cannot be reliably or consistently measured. Thus, although research has enabled the identification of a few environmental factors that lead to a predisposition to disease, in comparison, an explosion of knowledge has occurred about the genetic contribution to many rheumatic diseases.

## EVIDENCE FOR A GENETIC COMPONENT TO RHEUMATIC DISEASES

To justify an investigation of the genetic basis of any disease, it is first necessary to have some evidence that genes play a role in the disease. This evidence most commonly comes from twin or family studies, although findings of adoption and migration studies can also support a genetic component. Classic twin studies compare the incidence of disease concordance in monozygotic (MZ) and dizygotic (DZ) twin pairs. Higher disease concordance in MZ twins provides support for a genetic cause and can be used to estimate the heritability of disease. The concordance of disease in MZ twins at one point in time will underestimate the genetic contribution to risk in diseases that generally feature a late age at onset, such as many musculoskeletal disorders, because as time progresses, the concordance rate in MZ twins is likely to increase as their age increases. Thus the concordance rate from one twin study in the United Kingdom was 15% in MZ twins versus 4% in DZ twins, equating to a 60% heritability.[1]

For less common rheumatic diseases, it may be impossible to collect enough data on twin pairs to interpret the data reliably. However, family studies can also indicate a genetic contribution to disease. The sibling recurrence risk ratio is defined as:

$$\lambda_s = \frac{\text{Risk of recurrence in a sibling of affected individuals}}{\text{General population risk}}$$

Diseases that show an increased prevalence in family members are likely to have a genetic component. Obtaining a reliable value of $\lambda_s$ depends on having accurate estimates of disease prevalence in the two comparison groups, which is not a trivial matter. A firm diagnosis of rheumatic disease is difficult to make in large population surveys, with errors possible in both directions. Underestimation may occur because of the lack of reporting of disease that is no longer active, and overestimation may result from inadequate distinction among different forms of rheumatic diseases. Table 21-1 shows the heritability estimates (where available) and sibling recurrence risk ratios for some rheumatic diseases.

If genome-wide genotype data are available, it is now also possible to estimate heritability from the data itself using statistical methods that assume that patients with a disease are more genetically similar overall than control subjects, a process called genome-wide complex trait analysis (GCTA).[2] However, in some cases the genetic data can suggest lower heritability than the original twin/family estimates; for example, an estimation of "callous-unemotional" behavior based on twin study methodology yielded a heritability estimate of 64%, compared with genomic sequencing that yielded a heritability estimate of 7%.[3]

## STUDY DESIGN

A number of important considerations exist when designing a study to identify genetic variants contributing to disease. These considerations include the use of linkage

(Table 21-2) versus association approaches, case-control versus family-based studies, the choice of marker to be tested, and candidate gene versus whole genome methods. The choice may be driven by cost considerations, power, and/or the availability of samples. The differing approaches are outlined in the following sections.

## Linkage Studies

Linkage methods depend on the ability to track polymorphic markers in families and to show that these genetic markers co-segregate with the disease phenotype in families in which multiple members are affected. Thus multiplex families are required for linkage analysis. The details of the statistical methods are complex but are in general based on examining the likelihood of a particular pattern of co-inheritance of marker and disease (linkage) compared with the likelihood that there is no linkage (the null hypothesis). A measure of this likelihood is referred to as the log of the odds (LOD) score, with a LOD score greater than 3 generally interpreted as indicating significant evidence of linkage when markers across the entire genome are examined. Ott and Bhat[4] described linkage methods in detail in 1999.

**TABLE 21-1** Sibling Recurrence Risks and Heritability Estimates for Some Common Rheumatic Diseases

| Rheumatic Disease | Sibling Recurrence Risk | Heritability (%) |
|---|---|---|
| Rheumatoid arthritis | 3-19 | 60 |
| Juvenile idiopathic arthritis | 15-20 | |
| Psoriatic arthritis | 40 | |
| Ankylosing spondylitis | 54 | >90 |
| Systemic lupus erythematosus | 20-40 | 66 |
| Osteoarthritis | | |
| Hip | 2-4 | 60 |
| Knee | 2-5 | 40 |
| Hand | 4 | 60 |

One advantage of linkage analysis is that the entire genome can be effectively interrogated by using less than 500 informative microsatellite markers, or approximately 5000 single-nucleotide polymorphism (SNP) markers. Linkage analysis has been applied with great success to the analysis of rheumatic diseases that exhibit a clear Mendelian pattern of inheritance (e.g., dominant or recessive). For example, in 1992, familial Mediterranean fever was mapped to chromosome 16,[5] and this mapping led to the identification of the gene for this disease in 1997.[6] In addition, an entirely new class of familial periodic fever syndromes has been localized to mutations in the tumor necrosis factor (TNF) receptor 1 gene on chromosome 12.[7] Thus, for highly penetrant Mendelian disorders, classic linkage analysis is a powerful means of identifying the underlying molecular basis of disease. However, one of the drawbacks to classic linkage analysis is that, to be most useful, it should be applied to disorders with a high penetrance and a known genetic model (e.g., dominant vs. recessive). An alternative approach based on linkage, broadly called *allele sharing*, is preferred for the study of musculoskeletal diseases that have a complex genetic basis.[8]

The most common approach to allele sharing is the affected sibling pair (ASP) method. This method is based on a simple question: When two siblings are both affected with a disease, do they share alleles at particular genetic markers more frequently than would be expected by chance? Figure 21-1 illustrates this basic approach. In this family, two siblings are affected and the first-born sibling (sibling 1) has inherited alleles 1 and 3 at a marker locus, X. By the laws of Mendelian inheritance, sibling 2 has a 25% chance of inheriting these same two alleles and a 25% chance of inheriting neither of these alleles (i.e., sibling 2 inherits 2,4 or shares nothing with sibling 1 at locus X). By a similar reasoning, there is a 50% chance that these two siblings will share one allele in common. This 25:50:25 distribution of sharing zero, one, or two haplotypes is expected if there is no linkage between the disease and the marker locus. However, if a gene that lies near the marker locus is involved in disease risk, a significant deviation toward increased sharing among affected siblings will be observed. The closer

**TABLE 21-2** Glossary of Terms

| | |
|---|---|
| Allele | Alternative form, or variant, of a gene at a particular locus |
| Alloantisera | Antisera that detect antigenic differences between individuals in the population; the term is most often used to refer to sera that detect antigenic (i.e., structural) differences among human leukocyte antigen molecules carried by different individuals |
| Haplotype | A group of alleles at adjacent or closely linked loci on the same chromosome that are usually inherited together as a unit |
| Heterozygote | An individual who inherits two different alleles at a given locus on two homologous chromosomes |
| Heterozygosity | A measure at a particular locus of the frequency with which heterozygotes occur in the population |
| Linkage | The tendency toward the co-inheritance within a family of two genes that lie near each other on the genome; complete linkage occurs when parents who are heterozygous at each locus are unable to produce recombinant gametes |
| Linkage disequilibrium | The preferential association in a population of two alleles or mutations that occurs more frequently than predicted by chance; linkage disequilibrium is detected statistically, and except in unusual circumstances, it implies that the two alleles lie near each other on the genome |
| Polymorphism | The degree of allelic variation at a locus within a population; specific criteria differ, but a locus is said to be polymorphic if the most frequent allele does not occur in >98% of the population; occasionally, polymorphism can be used in the same way as allele to refer to a particular genetic variant |
| Penetrance | The conditional probability of disease (or phenotype) given the presence of a risk genotype |

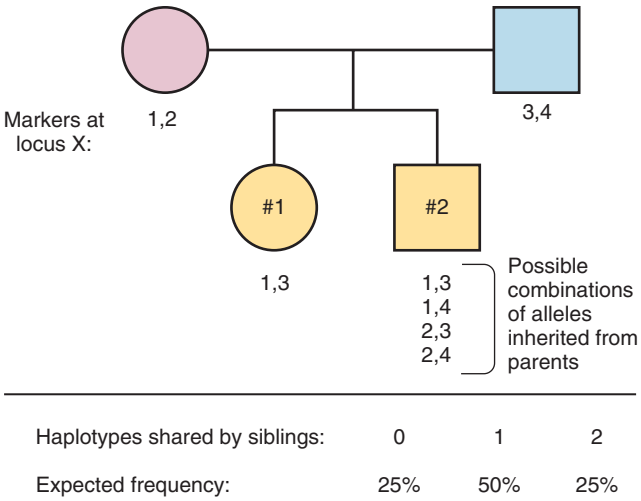

**Figure 21-1** A nuclear family with two affected children (affected sibling pair). The possible distribution of alleles at an autosomal locus, X, is shown for sibling 2, along with the predicted frequency of shared haplotypes among the siblings. In these families, researchers can detect linkage using affected sibling pair analysis (see text).

the marker is to the disease locus, the greater the deviation will be from a 25:50:25 distribution. By examining large numbers of affected sibling pairs in this manner, the investigator can develop statistical evidence that this is the case using a standard $\chi^2$ analysis, with the null hypothesis being that there is no increased sharing at the marker locus.

ASP analysis has a number of distinct advantages and disadvantages. Because only affected individuals are used, the problem of falsely assigning a family member as "unaffected" is eliminated, which is a major issue for many musculoskeletal diseases in which the disease may not express itself until later in life. ASP analysis also can be performed without assuming a specific model of inheritance (i.e., recessive or dominant). However, as with linkage in general, the ASP methods are limited in that they have relatively low power to detect genes that confer only modest risk. As a result, large numbers (hundreds or thousands) of families with affected siblings are required to obtain statistically significant results (see Figure 21-1).

Linkage analysis based on allele sharing began to be applied to genetically complex rheumatic and autoimmune diseases in the 1990s and has resulted in a few successes, most notably the identification of the *NOD2* gene as a major risk factor for Crohn's disease.[9,10] Linkage analysis has provided evidence for numerous risk genes involved in systemic lupus erythematosus (SLE).[11] The presence of a linkage peak (LOD score >3.5) on chromosome 2q in rheumatoid arthritis (RA) ASPs[12] led to the identification of the *STAT4* gene as a risk gene for RA and SLE.[13] Thus, although linkage is challenging to carry out, occasionally it can be applied successfully to complex diseases that do not have a clear Mendelian pattern of segregation.

## Population-Association Studies and the Calculation of the Odds Ratio, an Estimate of Relative Risk

The ideal way to establish whether a genetic variant (allele) confers risk for a disease is by performing a prospective cohort study. In this type of study, a group of individuals carrying (exposed to) the risk variant is compared with a matched control group that does not carry the risk variant. These two groups are followed up over time (preferably over a lifetime) to see if disease develops more frequently in the exposed group. The results can be displayed in a contingency table (Table 21-3). By examining the upper half of Table 21-3, it is apparent that the fraction of exposed individuals who get the disease is a/(a + b), whereas the fraction of unexposed individuals who get the disease is c/(c + d). The ratio of these two fractions is known as the relative risk (RR): a/(a + b) ÷ c/(c + d) = (ac + ad)/(ac + bc). If the disease is rare in the population, ac is small and the RR is approximated by (a × d)/(b × c), also referred to as the *cross-product*. In reality, such prospective cohort studies are usually impractical, and therefore a retrospective case-control design is used. In this type of study, subjects are initially identified according to whether they have the disease, and persons without the disease are the control subjects. The data can be tabulated as in the lower half of Table 21-3. In this case, the cross-product or (a × d)/(b × c) is known as the odds ratio (OR). In practice, this quantity is often reported as the estimated RR because the cross-product is close to the RR when the disease is rare. An OR of 1 indicates that the genetic factor confers no risk for the disease. An OR less than 1 suggests that the genetic factor under study is negatively associated with the disease (i.e., it is protective). Traditionally, ORs are reported with respect to the less common genetic variant (minor allele), and thus an OR of less than 1 indicates that the major allele confers risk. Sometimes, however, the OR with respect to the risk variant (whether the major or minor allele) is reported, and in that case, the OR is always greater than 1 if the result is statistically significant.

**TABLE 21-3** Contingency Table for Cohort and Case-Control Studies*

**Cohort Study**

| | Disease | No Disease |
|---|---|---|
| Exposed | a | b |
| Not exposed | c | d |

**Case-Control Study**

| | Exposed | Not Exposed |
|---|---|---|
| Disease | a | b |
| No disease | c | d |

*The letters a, b, c, and d represent the number of persons observed in each category.

One of the potential drawbacks of case-control association studies is that spurious association can occur if the case subjects and control subjects are not sampled from the same population (population stratification)—for example, if all subjects with disease were from a Scottish population and all control subjects were from a Spanish population. The gene variant conferring red hair color is more prevalent in the Scottish population with or without disease. Therefore, the red hair color gene would be associated with disease in such a study, but the association would be a false positive. In reality, if information is available on a large number of

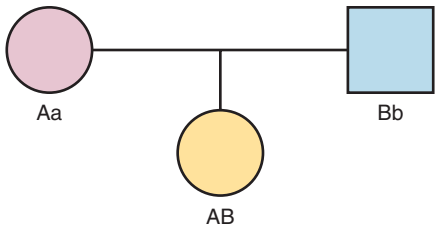

**Figure 21-2** Illustration of the trio family used for transmission disequilibrium test analysis.

genetic variants across the genome or for variants known to differ across populations of different ancestry, it is possible to correct for population stratification in the analysis, but the best solution is to consider this potential confounder in the study design.

## Family-Based Versus Case-Control Approaches

Family-based control subjects can also be used for genetic association studies. Consider the family shown in Figure 21-2. The affected child carries alleles A and B, each of which is inherited from one parent. The laws of Mendelian inheritance specify that one allele from each parent is not inherited by any given offspring—in this example, a in the father and b in the mother. These two noninherited haplotypes can be thought of as forming a genotype for a "control" individual. In this manner, issues of population stratification (see earlier) are eliminated because patients and control subjects are sampled from the identical (parental) gene pool. Falk and Rubinstein[14] originally proposed this approach to disease association and called it the *haplotype RR method*. Its validity depends on a number of assumptions, including that the genetic marker under study does not influence mating preference or the production of gametes. An extension of this approach is called the *transmission disequilibrium test* (TDT).[15] Using the family in Figure 21-2, for a given heterozygous parent (such as the father carrying a,c), there is a probability of 0.5 that any given allele, such as "a," will be transmitted to the child. If the "a" allele has no bearing on disease risk, the probability of transmission (T) to an affected child is equal to the probability of nontransmission (NT). This can be stated simply as P (T/D) = P (NT/D), in which D indicates the presence of disease in the offspring. However, if the allele being examined is associated with disease risk, then the following equation applies: P (T/D) > P (NT/D). If large numbers of heterozygous parents with affected offspring are examined, the TDT can establish an association between disease and the test allele compared with the (noninherited) control alleles. Although the TDT is an elegant solution to getting around the issue of population stratification, it is generally more expensive to identify and genotype trio families, and the TDT has less statistical power than a standard case-control approach to association (Figure 21-2) .

## Choice of Genetic Marker to Test

An explosion in new genetic knowledge has occurred during the past few years and is likely to continue for some time. A major foundation was laid by the completion of the Human Genome Project,[16] which provided a draft reference sequence for the entire 3.2 billion base pairs of the human genome. Subsequently, the human HapMap Project (http://hapmap.ncbi.nlm.nih.gov) has provided a catalog of the common sequence variation across the human genome. The most common form of variation across the genome is where a single base change occurs—for example, from adenine (A) to guanine (G) in the DNA sequence. Such changes are called SNPs, and more than 30 million SNPs are now referenced for *Homo sapiens* in dbSNP, an online SNP reference database (www.ncbi.nlm.nih.gov/SNP). In addition to SNPs, there are tens of thousands of variable numbers of tandem repeats (VNTRs) variants, a common form of which is termed a *microsatellite*. Microsatellites were used extensively for linkage analysis in the era before genome-wide association studies (GWAS) with SNPs. Large insertions and deletions are also quite common across the genome, some of which arise de novo,[17] providing yet another source of individual genetic variation that can be associated with human disease. For example, Huntington's disease is caused by a variable number of repeats of a CAG triplet within the Huntington gene. Smaller insertions and deletions are just beginning to be cataloged, and thus the number of these genetic variants will grow substantially as more human genomes are fully sequenced.

## Candidate Gene Versus Genome-wide Association Studies

The first wave of genetic studies of complex diseases focused on candidate gene studies. The candidate genes investigated were selected either on the basis of biologic plausibility, because they were associated with another disease, or on the basis of animal model studies. However, the previous probability of detecting an association to one gene among at least 30,000 known protein-coding genes was very low, especially when only one or a few markers were tested at the genomic locus, as was generally the case in such candidate gene studies. Furthermore, few studies tested large sample sizes of case and control subjects, and thus they were underpowered to generate robust findings. Nonetheless, several genes of large effect sizes were robustly and consistently detected, notably the *HLA* and *PTPN22* genetic associations observed with many complex diseases.

The acceleration in the knowledge of genetic variation across the genome due to initiatives such as The HapMap project, coupled with sweeping technologic advances, have meant that it is now possible to test SNP markers spanning the genome for evidence of association, so-called GWAS. The era of SNP-based GWAS began in earnest in 2005, when the complement regulatory protein factor H was identified as a significant risk factor for age-related macular degeneration.[18] Shortly thereafter, a second major GWAS led to the identification of the interleukin (IL)-23 receptor as a risk gene for Crohn's disease.[19] A major advance was made in 2007 with the realization that for most complex diseases, effect sizes of individual variants on disease would be modest, and hence large sample sizes would be required to robustly detect association. This advance was heralded by the pioneering Wellcome Trust Case Control Consortium (WTCCC) study.[20] The WTCCC study was the first

to use a respectably powered study design, including 2000 cases from seven diseases and 3000 common control subjects. Association was tested to 500,000 SNP markers spanning the genome, and robust statistical thresholds were applied to claim confirmed significance. Novel loci were identified and subsequent, better powered studies in larger independent sample sizes identified further loci. In the intervening 10 years, GWAS have proven to be particularly fruitful when applied to autoimmune disorders. Together, nearly 200 distinct chromosomal regions have now been identified as containing risk loci for major autoimmune diseases (https://www.genome.gov/26525384). As large datasets are assembled for some of the rarer or less studied autoimmune disorders, GWAS will continue to play a major role in dissecting the genetic contribution to musculoskeletal diseases.

## Genome-wide Association Studies

Compared with linkage analysis, association methods have much greater statistical power to detect genetic effects.[21] However, in contrast to the relatively modest numbers of markers used for linkage studies, hundreds of thousands or even millions of genetic markers are currently used to carry out GWAS using association methods. For scanning the entire genome, GWAS have generally replaced linkage methods except in special situations in which large multiplex families suggest the presence of a Mendelian pattern of inheritance.

The issue of testing so many markers raises the possibility of detecting association by chance alone. Hence, the genetics community has implemented thresholds for claims of confirmed association, based on the fact that there are estimated to be 1 million independent (noncorrelated) SNPs across the genome; applying a Bonferroni correction for 1 million markers equates to exceeding a statistical threshold of $P < 5 \times 10^{-8}$ to report confirmed association. In turn, this has implications for study power and is related to the effect size of the locus, the statistical threshold, and the frequency of the risk allele, which all have an impact on the sample size required to detect association. Thus the smaller the effect size expected, the lower the *P* value threshold used, and the lower the frequency of the minor allele, the larger the sample size required to have power to detect association. The effect size reflects the contribution of a particular locus to disease susceptibility and is measured by the OR. ORs are often overestimated in the first study in which a locus is reported to be associated with a disease because of the phenomenon of "winner's curse,"[22] because most studies are underpowered to detect all susceptibility loci. If association is detected, it is likely that, by chance, the risk allele is enriched in the population tested. In independent populations, the true frequency of the risk allele will be lower so a larger sample size is required to replicate the association.

The success of whole genome association studies is critically dependent on taking advantage of the underlying haplotype structure of the genome, which in turn reflects the ubiquitous presence of linkage disequilibrium (LD) across the genome. LD is discussed in greater detail in the next section and refers to the fact that genetic variants at adjacent loci often tend to be found together more frequently than expected by chance. LD over long distances is a particularly prominent feature of the human leukocyte antigen (HLA) region, especially for certain haplotypes.

### Linkage Disequilibrium

The concept of LD is central to understanding the significance of any genetic association with disease. LD exists when the frequency of two alleles occurring together on the same haplotype exceeds that predicted by chance. For example, a common major histocompatibility complex (MHC) haplotype that exhibits LD in the white population carries a certain combination of alleles, A*0101-B*0801-DRB1*03011, commonly referred to as the A1-B8-DR3 haplotype, and more recently designated the "8.1" haplotype.[23] This haplotype is present in approximately 9% of the Danish population, a typical white Northern European group. To understand why this reflects the presence of LD, consider the fact that the A1 allele is present in 17% of Danes and the B8 allele is present in 12.7% of Danes. They could be expected to be found together only 12.7% × 17% = 2.1% of the time, much less than what is observed (9%). This simple difference between the expected and observed association between alleles is a measure of LD, known as *D*; in this case D = (0.09 – 0.021) = 0.069. Table 21-4 provides the general calculation of D for a simple two-locus, two-allele situation. Because the magnitude of D is strongly influenced by the relative frequencies of the various alleles, normalized measures of LD are used in practice, including D′ and $r^2$, as described in Table 21-4.

It is useful to understand these measures of LD because detailed maps of LD are widely available online for the entire human genome, with visualization tools that are easy to use (see http://hapmap.ncbi.nlm.nih.gov). The lower portion of Figure 21-3 shows a visualization of LD using the D′ measure for a region around the *PTPN22* gene on chromosome 1. The D′ value between any two markers is reflected by the heat map (red D′ = 1; white D′ = 0). In this case, LD extends well beyond *PTPN22* itself. Indeed, as indicated in Figure 21-3, the SNP marker rs6679677 was used by the WTCCC[20] to detect the underlying association of RA with *PTPN22*, even though this marker is 100 kb distant from the causative SNP at rs2476601, which lies within the *PTPN22* gene.

To understand how LD occurs, it is useful to remember that, during meiosis, recombination occurs, resulting in a shuffling of the genome. An analogy is shuffling a pack of cards. Three likely explanations for LD exist. First, the population may have originated from a mixture of two populations, one of which had a high frequency of a particular haplotype. If this phenomenon happened recently, there would not have been time (i.e., a sufficient number of generations) to randomize alleles at closely linked loci by recombination at meiosis, which is known as population admixture. In the analogy of the playing cards, consider the situation of two suits of cards (diamonds and spades, for example) that have been shuffled together less than 10 times to mix them. When the cards are dealt, there will be large runs of sequential cards of the same suit. Inasmuch as human history is marked by large population migrations, it is probable that population admixture explains many examples of LD. A second explanation, related to the first, rests

**TABLE 21-4** Measuring Linkage Disequilibrium

Consider a region of a chromosome with two adjacent loci, A and B. At each locus, there are two possible alleles, 1 and 2. Four combinations of alleles, or haplotypes, are possible. These possible combinations are shown below, including a color bar representation and designations for the frequency of these haplotypes in the population.

$A_1$____$B_1$  frequency = $x_{11}$
$A_1$____$B_2$  frequency = $x_{12}$
$A_2$____$B_1$  frequency = $x_{21}$
$A_2$____$B_2$  frequency = $x_{22}$

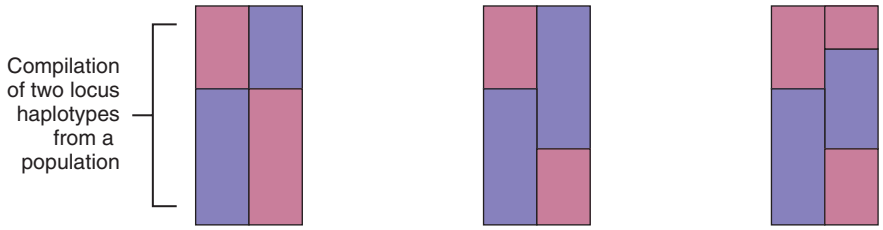
Designate the allele frequencies at locus A as $p_1$ and $p_2$.
Designate the allele frequencies at locus B as $q_1$ and $q_2$.

Then

$p_1 = x_{11} + x_{12}$
$p_2 = x_{21} + x_{22}$
$q_1 = x_{11} + x_{21}$
$q_2 = x_{12} + x_{22}$

A simple measure of D is then calculated as $D = x_{11} - p_1 * q_1$. This value directly measures the difference between the observed haplotype frequency (in this case $x_{11}$) from that expected from random association of the alleles at each locus (in this case $p_1 * q_1$). For any allelic combination in a given dataset, the magnitude of D will be the same, although the sign (+ or –) may change according to the direction of the allelic association on the haplotypes.

A more standardized measure of D is more useful in practice and is designated D′. D′ is the ratio of the observed D to the maximal (or minimal) possible value of D given the observed allele frequencies.



$$D' = \frac{D}{D_{max}} \text{ when } D \geq 0 \quad \text{and} \quad D' = \frac{D}{D_{min}} \text{ when } D < 0.$$

D′ can therefore take on values between 0 and 1, and it is a measure of linkage disequilibrium (LD) that is normalized for variations in allele frequencies at the two loci.

Another useful measure of LD is the correlation coefficient, $r^2$, between alleles at A and B. Like D′, the value of $r^2$ can also vary between 0 and 1. However, unlike D′, the value of $r^2$ is a more global measure of how alleles at the two loci are associated and is given by:

$$r = \frac{D}{\sqrt{p_1 p_2 q_1 q_2}}$$

When $r^2$ is = 1, there are only two possible haplotypes, and knowing the allele at locus A is completely predictive of the allele present at locus B. In this case, D′ also = 1. However, D′ can = 1 when $r^2 < 1$. In this case, there will only be three possible haplotypes in the population. If D′ is < 1, there will be four haplotypes in the population, which is illustrated in the colored two-locus phased haplotype displays shown below.

A presentation of phased haplotypes similar to these is shown for the region around the *PTPN22* gene in Figure 21-3.

on the observation that certain regions of the genome tend to exhibit relatively low levels of meiotic recombination (i.e., in the card analogy, for some reason, some cards are never separated by shuffling but are stuck together) for reasons related to the underlying genomic structure. Thus genetic variants within these regions tend to stay together on the same haplotype over many generations, even if haplotypes were introduced into a population in the distant past. The importance of this concept for understanding LD is still under active debate in the genetics community.

A third explanation for LD posits that the alleles in LD may be maintained together because of a selective advantage. For example, going back to the A1-B8-DR3 haplotype mentioned earlier, one could postulate an advantage for immune defense when alleles on this haplotype are maintained and regulated together in the same individual. Thus individuals with this haplotype may have had a survival advantage in times when infection in childhood was the greatest cause of death. The haplotype would become more common in the population, but now that people are surviving into in older age, the same haplotype may predispose to autoimmune disease as a result of a heightened immune response. Although plausible, this hypothesis is difficult to prove for any particular haplotype.

LD is useful for mapping associated variants because, as Figure 21-3 shows, for the region around the *PTPN22* gene

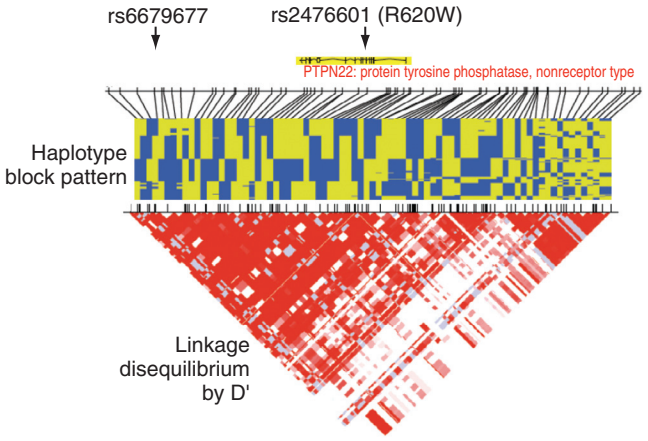


**Figure 21-3** Map of the region around the *PTPN22* locus on chromosome 1p13 covering approximately 200,000 base pairs. The blue and yellow haplotype pattern in the central part of the figure was generated by looking at combinations of single-nucleotide polymorphism (SNP) alleles in 90 white subjects from the HapMap Project. It is analogous to the presentation of linkage disequilibrium discussed in Table 21-7. Note that despite the large number of SNPs, a limited number of haplotype patterns are observed, generating a kind of bar code for each subject. The lower portion of the figure shows a heat map in which the intensity of the red color reflects the degree of correlation (linkage disequilibrium [LD] measured by D′) among SNPs across the region (indicated by *tick marks*). Note that widely separated SNPs are highly correlated. Two markers associated with type 1 diabetes (and other autoimmune diseases) are shown at the top. Marker rs2476601 is likely to be the causative variant in this region and results in an amino acid change at codon 620. Note that another marker (rs6679677) nearly a distance of 100 kb also strongly associates with diabetes, emphasizing that it is difficult to assign the causative locus on the basis of associations alone when extensive LD exists in a region.

on chromosome 1, common variations in large segments of most genetic regions can be interrogated using just a few markers that "tag" the common haplotypes. One can think of these patterns of haplotype variation as a kind of bar code of common haplotypes across a genomic region, as shown in the central region of Figure 21-3 and described in Table 21-4. As previously mentioned, the International HapMap Project has established online resources that allow users to easily explore the haplotype structure of any region of the genome. The HapMap Web site also contains informative tutorials on genetic diversity and the use of this resource.

## Common Versus Rare Variants

Debate continues about the overall genetic "architecture" of human disease.[24] Until recently, it was assumed that common allelic variants are likely to account for a large portion of the genetic risk for common diseases in the population. This assumption was based on the "common disease, common variant" hypothesis that assumes that common diseases will be caused by variants in the population that do not individually have a large effect on disease risk and thus are common in the population.[25] If a variant had a large effect on disease risk, it would be likely to reduce reproductive fitness and therefore would not survive over generations, and thus its frequency would be rare. The fact that common diseases are common suggests that the variants that cause them do not affect reproductive fitness and thus would be expected to persist over generations and be frequent in the population. By common variants, we generally mean variants that are present in the population at frequencies of 5% or more, and certainly not less than 1%.

Findings from many complex diseases provide partial support for this theory; for example, the HLA alleles and the *PTPN22* gene variant that are associated with many rheumatic diseases are examples in which the risk variants occur at a reasonable frequency in the population. However, the common variants identified to date do not explain all of the genetic contribution to disease, and there is no a priori reason to reject the hypothesis that many rare variants actually account for a significant fraction of the genetic burden of disease. The main reason that common variants have been a focus of research is because the current technologies are particularly well suited to investigating them. Therefore, the common disease, common variant hypothesis currently is a self-fulfilling prophecy because the technology platforms have focused on testing common variants. This situation is about to change with the advent of new technologies that permit resequencing on a massive scale. Routine sequencing of entire individual human genomes is probably not more than 5 years away, and examples of rare variants contributing to musculoskeletal diseases are already beginning to emerge.[26] This advancement in turn has stimulated the development of sophisticated statistical approaches to the analysis of large datasets, while at the same time highlighting the need to integrate the genetic knowledge with clinical data in ways that are manageable and meaningful to researchers and, ultimately, to practitioners. The imminent availability of massive genetic datasets now mandate new, more efficient ways to store and analyze the data. Thus we are still relatively early in the whole genome era of genetic mapping.

## Interpreting Statistical Association from Case-Control Studies

Almost all of the studies of complex diseases in recent years have reported statistical associations that are detected by means of retrospective case-control studies. It is essential to understand the strengths and weaknesses of this approach to genetic analysis to judge the significance of these associations.

In general, there are three possible reasons for detecting an association between a particular allele and a disease, once acceptable statistical criteria are met (see preceding text). First, the allele under investigation may be directly involved in the pathogenesis of the disease. A second reason that must be considered is the possibility that the result is an artefact of population stratification of patients and control subjects. The specific concern is that the control group may not be genetically matched to the disease group at loci that are unrelated to disease, which often results from a failure to study a control group that is ethnically matched to the disease group. This lack of genetic matching is generally a major issue in genetic case-control studies, and several approaches to address this issue have been proposed,[27] including the use of panels of genetic markers that specifically reflect ethnic background. These methodologies for correcting for underlying population genetic substructure are now widely accepted and are often required for publication in leading genetics journals. It is generally not adequate

to accept self-reported ethnicity as a basis for matching cases and control subjects.

Finally, a third (and common) reason for observing a genetic association is that the causative gene is actually in LD with the marker allele being tested, be it an SNP or a particular HLA variant. Therefore, once an association signal is detected, further fine mapping is required to locate the markers with the greatest evidence of statistical association and explore whether these variants could be functional and, therefore, causal.

## Rheumatoid Arthritis Susceptibility Genes

Before the GWAS era, researchers could with confidence assign only two loci—the *HLA-DRB1* and *PTPN22* genes—as having a role in the risk of susceptibility to RA, and they are still the largest genetic risk factors known to date for RA. As with the majority of autoimmune diseases, the HLA region confers, by far, the largest genetic risk for RA, accounting for approximately 60% of the genetic load. This large effect size enabled robust conclusions to be made regarding the involvement of the HLA region in RA some 30 years before the modern genetic era, using quite modest sample sizes.

## Class I and Class II Human Leukocyte Antigen Isotypes: Functional Correlates

Class II HLA molecules have a restricted tissue distribution that is generally limited to antigen-presenting cells of the immune system, such as B cells, macrophages, dendritic cells, and some subsets of T cells. This phenomenon reflects the fact that class II HLA molecules are primarily involved in presenting foreign antigens to $CD4^+$ T cells during the initiation and propagation of the immune response. However, the expression of class II HLA molecules can also be induced on a variety of other cell types by inflammatory cytokines such as interferon (IFN)-γ, enabling these cells to engage in antigen presentation to $CD4^+$ T cells. In contrast, class I HLA molecules are widely distributed on all somatic cells, with the exception of red blood cells. This distribution reflects their predominant role in presenting antigen to $CD8^+$ effector or cytotoxic T cells.

Another major functional difference between class I and class II molecules is related to the source of peptide antigens that are found in the antigen-binding cleft. In general, class I molecules present peptide antigens derived from proteins that are actively synthesized within the endoplasmic reticulum, whereas class II HLA molecules present antigens that are taken up from outside of the cell by endocytosis. These differences are reflected in the antigen-processing machinery and the different trafficking patterns of class I and class II molecules inside the cell. This complex process is discussed in detail in Chapters 10 and 18.

## Rheumatoid Arthritis: *HLA-DRB1* Associations and the "Shared Epitope"

Stastny[28] reported the first associations of RA with class II HLA alleles in the 1970s. This work was performed using cellular and antibody reagents that are no longer routinely used for HLA typing; however, the nomenclature for HLA alleles still derives from these early typing methods. The *DRB1*0401* allele (corresponding to the "Dw4" type in Stastny's original report) was the first HLA polymorphism to be associated with RA. Numerous studies have generally confirmed that this allele is the most strongly associated with RA, at least in white populations. However, several other *HLA-DRB1* alleles have also been associated with RA, although the strength of these associations varies. In some ethnic groups, RA is not associated with *HLA-DR4* alleles but rather with *HLA-DR1*[29] or *HLA-DR10*.[30] Experts now widely accept that the following alleles are the major contributors to RA risk at the DRB1 locus: *DRB1*0401*, **0404*, **0405*, **0101*, and **1001*. In addition, minor variants of these alleles and others (e.g., *DRB1*1402*) may also contribute to susceptibility, and *DRB1*0901* is a susceptibility allele in Asians, where this allele is common. Most of these risk alleles share a common sequence, as shown in Table 21-5. This consensus amino acid sequence—Q or K-R-R-A-A—has been termed the *shared epitope* (SE).[31] This structural feature is located in the third hypervariable region on the α-helical portion of the DR β chain in a position where it may influence both peptide binding and T cell receptor (TCR) interactions with the DRB1 molecule. In the case of the *DRB1*1001* risk allele, one amino acid varies from this consensus by a conservative change, with an R at position 70, as does *DRB1*0901*, which is commonly associated with RA in Asian populations (Table 21-6).

A number of different hypotheses have been advanced to explain the SE association with RA. Given that this region of the genome codes for amino acids that sit within

**TABLE 21-5** Genotype Relative Risks of DRB1 Genotypes for Rheumatoid Arthritis

| DRB1 Genotype | Relative Risk | *P* Value |
|---|---|---|
| 0101/DRX | 2.3 | $10^{-3}$ |
| 0401/DRX | 4.7 | $10^{-12}$ |
| 0404/DRX | 5 | $10^{-9}$ |
| 0101/0401 | 6.4 | $10^{-4}$ |
| 0401/0404 | 31.3 | $10^{-33}$ |

**TABLE 21-6** Amino Acid Substitutions that Compose the Shared Epitope at Positions 70 through 74 of DRB1 Alleles Associated with Rheumatoid Arthritis

| | AMINO ACID POSITION | | | | |

| 1001 | Arg | — | — | — | — |

and inform the shape of the groove of the DRB1 protein responsible for binding and presenting foreign bodies (antigens) to the immune system, an obvious possibility is that a specific RA antigen, probably an autoantigen, is being presented to the immune system in such a way as to illicit an erroneously controlled immune response, leading ultimately to the inflammatory destruction of joint tissue. Many years of investigations have failed to convincingly demonstrate the RA autoantigen presented by the shared epitope, although many antigens have been suggested as possibilities. In view of the strong association of the SE alleles with anti-citrullinated protein antibodies (ACPA), it is of interest that citrullinated peptides may have a particular affinity for *DRB1*0401* alleles.[32]

A second major hypothesis posits that these risk alleles regulate the formation of the peripheral T cell repertoire by acting to select for particular TCRs during thymic selection. Elegant experimental evidence in humans supports a role for DR4 alleles in shaping the peripheral T cell repertoire.[33] However, it is unclear whether this effect on the TCR repertoire is really related to disease susceptibility. Researchers have proposed a number of other interesting hypotheses, involving molecular mimicry,[34,35] allele-specific differences in intra-cellular trafficking,[36] and regulation of nitric oxide production,[37] but these hypotheses require further experimental confirmation.

The SE hypothesis has come under scrutiny in recent years because it is quite clear that it is not a complete explanation for the *HLA* associations with RA, as indicated by the fact that not all SE-positive alleles carry the same degree of genetic risk; in addition, the strength of the association varies in different populations. In general, *DRB1*0101* alleles carry lower levels of RR for RA than the *DRB1*0401* and **0404* alleles,[38] and yet *DRB1*0101* is the major risk allele in some ethnic groups. The SE itself does not appear to associate strongly with RA in African American and some Hispanic populations.[39,40] Furthermore, certain combinations of *DRB1* alleles carry especially high risk.[41] Thus the combination of *DRB1*0401* with **0404* carries a RR of higher than 30 in Caucasian populations.[38] In comparison, RR values are in the range of 4 or 5 for either allele alone. Table 21-4 summarizes some of these relationships.

The idea of the SE involvement in RA, which was first suggested in 1987, is still largely correct but has been modified slightly in recent years. Using massively high throughput genetic technologies, coupled with powerful bioinformatic and statistical analysis, the association to RA in the *HLA-DRB1* gene has been refined to three amino acids that are independently associated with susceptibility to RA, with two of these amino acids located within the SE region.[42] Current understanding of the RA associations within the HLA region suggests that an amino acid at position 11 of *HLA-DRB1*—still within the peptide binding groove but not within the classical SE motif—is most associated with disease susceptibility, followed by two further associations at amino acids 71 and 74 within the SE. In addition, amino acids in *HLA-B* (at position 9) and *HLA-DPB1* (at position 9) also show robust association with RA, even after correcting for the association with HLA-DRB1 amino acids. Together, these five amino acids explain almost all of the association observed at the MHC genomic region in ACPA-positive European subjects with RA.

The other gene robustly associated with RA susceptibility in the premodern genetics era is *PTPN22*. In 2004, an association between the intra-cellular phosphatase, *PTPN22*, was reported for a number of autoimmune diseases including type 1 diabetes,[43] RA,[44] SLE,[45] and autoimmune thyroid disease.[46] With ORs consistently in the range of 1.5 to 2, this was the first compelling demonstration that a specific common allelic variant outside of the *HLA* gene region could confer risk for multiple different autoimmune phenotypes, and the finding has been consistently replicated.[47] In this case, a nonsynonymous change in one of several SH3 binding sites in PTPN22 (a tryptophan substitution for arginine at codon 620) was shown to disrupt the normal association of PTPN22 with a Csk, an intra-cellular tyrosine kinase.[43,44] Knockout of *PTPN22* in rodents leads to dramatic overactivity of T cells, but the exact functional consequence of the human risk allele remains controversial. However, there is little doubt that PTPN22 is involved in setting thresholds for TCR signaling through Lck,[48,49] as well as B cell receptor signaling.[50] PTPN22 is also found in many other hematopoietic cells, and its function in these cells is largely unknown.

Interestingly, all of the autoimmune diseases associated with *PTPN22* have a prominent autoantibody component, and thus a specific role in regulating humoral immunity appears to be a unifying feature. Notably, the *PTPN22* risk allele is actually protective for Crohn's disease and has no role in risk for multiple sclerosis, emphasizing the likely presence of distinct mechanisms of pathogenesis in these disorders.[51] This scenario offers a fascinating insight into disease mechanism and obviously has implications in areas such as drug development, where an agonist may well be effective for RA and other autoimmune diseases but may exacerbate Crohn's disease. Thus *PTPN22* is a prime example of how the discovery of new disease associations with relatively modest effect can redirect hypothesis-driven research into new pathways. The theme of common variants in genes that share susceptibility alleles across different diseases with common underling mechanisms begs the question of how these genetic variants affect the normal immune response. Do these genetic variants confer survival advantages? Could one examine the "normal" range of immune response phenotypes to detect a state of risk, without actually defining the complex underlying genetics? The entire issue of what constitutes the normal range of immune function has received renewed interest[52] and has driven interesting studies of the function of autoimmune risk loci in subjects without disease.[53] Indeed, the study of the normal immune system may be the key to understanding how complex arrays of risk alleles actually lead to disease in an individual.[54] Thus, in addition to further expansion of gene discovery efforts, advances in the genetics of autoimmunity are going to require more sophisticated ways of phenotyping the normal immune system, as well as the diseases themselves.

## The Genome-Wide Association Studies Era of Rheumatoid Arthritis Genetics

The step change in the rate of discovery of RA susceptibility genes was achieved in 2007 with the WTCCC[20] and followed from the huge advances in the knowledge of the

genetic architecture of the human genome and the enormous advancements in genotyping technology, enabling the design of chip arrays capable of analyzing more than 500,000 variants in a single experiment at a cost-effective price. It also coincided with the realization by the genetics community that large sample sizes of both cases and control subjects would be required to achieve adequate power and that new, robust statistical methodologies would need to be developed to analyze the resulting data. GWAS approaches have been improved over time, with ever greater numbers of genetic variants being analyzed in ever-increasing sample sizes, such that the latest RA genetic study incorporated 29,880 RA cases and 73,758 control subjects and brought the total number of confirmed genetic loci involved in susceptibility to 101.[55] We can learn much from the 101 loci currently known for RA:

1. *There are probably more genetic loci associated with RA left to discover.* It is notoriously difficult to estimate the true size of the genetic component of a complex disease like RA. The twin studies used to estimate the heritability of RA have been relatively small and have led to quite disparate estimates, but even using the lower estimates, the current confirmed genetic findings only account for approximately 60% of the genetic component of RA susceptibility. Many theories have been suggested for this "missing" genetic heritability,[56] including the role of epistasis, a multiplicative interaction between genes or between genes and environmental factors that confers greater risks than simple additive carriage alone. Other theories include the involvement of genetic variations, which have not yet been well investigated, such as copy number variants and rare variants. These types of variants generally are not well captured using current genotyping technologies. Epigenetics—that is, non–sequence-related changes to the DNA—may also play a role. It appears likely, though, that a combination of overestimating the genetic component of RA and the existence of many more genetic loci that contribute to the susceptibility of RA with ever-decreasing effect sizes are likely to play the major role in "missing" inheritance. A large number of genetic variants are strongly associated with disease susceptibility but at a significance level where findings cannot be claimed as confirmed ($P < 10^{-5}$ but $> 10^{-8}$). Studies of other diseases and traits (e.g., height and inflammatory bowel disease) have illustrated that the more samples that are tested, the more confirmed loci are obtained—a story found, and likely to be continued, in RA.[2,57]
2. *Not all risk variants are required in every patient.* The genetic variants that are being discovered to be associated with disease are generally quite common—that is, they are present in more than 5% of the population. As such, many people without disease have a "genetic risk score" and carry risk variants. Similarly, all patients will have a genetic risk score that is generally higher than that of control subjects but is based on carriage of a subset of risk variants, never all of them. Determining which specific variants are important in subsets of patients has the potential to stratify patients into more homogeneous subgroups, potentially with benefits for treatment therapy and outcome predictions. Statistical modeling has indicated that patients who carry a subset of risk variants (*HLA*, *PTPN22*, and *STAT4*) can have an OR of developing RA of greater than 15 compared with persons who do not have these variants.[58] This work and other continuing efforts will provide insights into the highest risk groups and their eventual outcome and response to different therapies.
3. *HLA associations are different in the serotypes of RA and, although they are by far the strongest genetic association, they are neither necessary nor sufficient to cause disease.* The long-established association of RA with the HLA locus gives us a great wealth of information about the disease. The vastly increased frequency of a distinct set of amino acids of the DRB1 locus in HLA suggests that the presentation of a common antigen is important in most but not all patients with RA. This situation is clearly distinct from that of other autoimmune diseases, which may be strongly associated with the HLA locus but with different genes or alleles. Furthermore, HLA-risk–negative patients with RA may be exposed to different environmental antigens that trigger the onset of disease. Indeed, evidence clearly indicates that ACPA seropositive and seronegative patients show association to different risk alleles within the *HLA-DRB1* gene, reflecting evidence that the amino acids themselves are different in seropositive and seronegative disease.[59] Similar to the landscape in seropositive disease, seronegative disease has independent genetic associations with both HLA class II *(HLA-DRB1)* and class I *(HLA-B)* genes. Again, the independent associations are seen at position 11 in *HLA-DRB1* and at position 9 in *HLA-B*, both within the peptide-binding grooves. These amino acid positions therefore have an association to both forms of disease, but importantly, the risk of seropositive and seronegative disease is to distinct amino acid residues, suggesting that separate antigens may be important in the different forms of RA. For example, Serine at position 11 was protective for $ACPA^+$ disease but conferred risk of $ACPA^-$ disease.[59] Along with other evidence that the genetic loci associated with the disease serotypes are different in both strength and effect,[60] the HLA locus provides compelling evidence that the two forms of disease are indeed genetically distinct. Within the seropositive subgroup, there is a hierarchy of risk dependent on the amino acid present at each of the five most important sites within the HLA locus, and this hierarchy of risk also correlates with disease severity (see reference 60a).[42]
4. *Both overlaps and clear differences exist between the genetic risk factors for RA in different populations and ethnicities.* The latest large-scale meta-analysis, which brought the confirmed number of genes associated with RA to 101, was an international study using large cohorts of Asian and Caucasian samples.[55] The study showed that many RA loci are shared among these groups, including key immune genes such as *IL6R*, *STAT4*, *TNFAIP3*, and *IRF5*. Although these loci are shared among patients with RA from different ethnic backgrounds, it is still to be established whether the same genetic variant is causal in both populations. Association with different causal genetic variants mapping to the same gene is observed in different autoimmune diseases; for example, different genetic variants within and around the *TNFAIP3* gene

are associated with both RA and SLE, but it is not clear whether this is true of RA in different populations.[61,62] If different causal variants were identified in different populations of the same disease, it would indicate that the gene is fundamental to disease susceptibility but that the genetic mutation arose on different ancestral backgrounds. Some genetic loci are shared between the two ethnicities, but as yet with no obvious candidate gene as the likely causal target. For example, strong associations with RA can be found to the promoter region of AFF3, a transcription factor with an unknown function in immune disease, in both the Asian and Caucasian populations.[55] Associated loci also exist that are population-specific, offering a fascinating insight into the different pathways, different evolutionary constraints, and different gene/environment interactions that may play a role in disease onset. These genes, surprisingly, include the *REL* gene, a subunit of nuclear factor-κB (NF-κB), which is a key driver of the immune response and a pathway strongly implicated in the majority of autoimmune diseases. The association at *REL* is only found in European populations and is absent in Asian cohorts. Other European-only susceptibility loci include *IL2RA*, *PRKCQ*, *CD5*, *CD28*, and *IFNGR2*. Loci restricted to Asian populations include *PRKCH*, *CD83*, and *IL3*, perhaps indicating disparate immune pathways that ultimately lead to RA in the different populations.

5. *Overlap exists between autoimmune diseases*. One of the remarkable findings in the modern genetic GWAS era has been the unexpected and significant overlap in genetic risk factors between different diseases, particularly among autoimmune diseases. In fact, this finding led to the instigation of a successful study to design a custom Illumina genotyping array—"immunochip"—that densely mapped the shared genetic loci in a wide range of autoimmune diseases, including RA, type 1 diabetes, inflammatory bowel disease, and celiac disease.[63,64] That study is the starting point for in-depth investigations as to the extent of genetic sharing between diseases, whether that be the same variant associated with groups of diseases or shared loci, but with different causal variants. Some of the most interesting insights may be gained by understanding which loci are associated uniquely with a particular disease. Already the analysis has offered a fascinating insight into cross-disease genetic risk. For example, although the majority of autoimmune diseases, including RA, share a risk variant within the *PTPN22* gene, the same variant is protective for Crohn's disease. Similarly, at the *IL6R* gene, a genetic variant protective for RA and cardiovascular disease confers risk for asthma. Interestingly, this variant is highly correlated with soluble IL-6R levels and functions by increasing the cleaving of IL-6R from the membrane bound to the soluble form. This increase in soluble IL-6R mimics the action of the therapeutic agent, tocilizumab, a soluble IL-6R agent used in the treatment of RA. For RA, the greatest overlap with disease currently appears to be with type 1 diabetes, although this outcome may be due to the larger sample sizes tested in these diseases, yielding larger numbers of confirmed associations. Perhaps the more interesting aspect of the genetic overlap between diseases is the genes that are unique to a disease. For RA it appears that only 2 genes of the 101 identified to date are unique to disease susceptibility. The first is the *PADI4* gene, which encodes a protein responsible for the citrullination of proteins and may be expected to be RA specific, given the specificity of ACPA autoantibodies in disease. More surprisingly, the gene encoding a general cytokine, CCL21, also seems to be uniquely associated with RA. This chemokine, which is responsible for the formation of lymph nodes (including tertiary, ectopic nodes) and T cell migration across lymph nodes, and has also been implicated in angiogenesis, may well explain the pannus formation and nodule formation characteristic of RA.
6. *Genetics can provide clues as to how disease is initiated and maintained, including the cell type that is the most important in disease initiation*. Both T and B cells have been implicated as the key drivers of RA. By studying the epigenetic marks that show regions of the DNA genome that are active in each cell type, it has been reported that there is an enrichment of RA genetic associations in regions of active DNA $CD^+$ T cells, implicating this cell type in susceptibility.[65] However, these findings are preliminary because it is becoming increasingly apparent that different regions of the genome are active under different conditions of stimulation and chronicities[66]; whether the enrichment of RA loci in active DNA regions in $CD4^+$ T cells will continue to be observed under these different conditions requires confirmation. Ongoing work will illuminate if, for example, a genetic change is more important in the synovial tissue to maintain disease progress from early inflammatory arthralgia to full-blown RA.

## Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is perhaps the most heterogeneous of complex rheumatic disorders. JIA is classified into several subgroups, incorporating number and chronicity of joint involvement, as well as comorbidity and autoantibody status. Although the subgrouping of JIA into classes may be contentious, clear delineation exists between the major classes. Subgroups exist that also have psoriasis, spine involvement, a systemic disease, and both antibody-positive and antibody-negative disease. It may be speculated that these subgroups are early forms of psoriatic arthritis (PsA), ankylosing spondylitis (AS), SLE, RA, and "true" JIA, and genetics has a clear role in gaining insight into the overlap between these forms of disease. In turn, this may inform a more rational or targeted approach to disease management.

The major genetic locus in the susceptibility to JIA is the *HLA* region, conferring up to 13% of the total genetic risk of disease.[67] Because of the genetic complexity of the *HLA* region and the difficulties in collecting sufficient sample sizes for each of the JIA subgroups to ensure adequate power to determine differences between subgroups, analysis of the *HLA* region in JIA lags behind RA but is ongoing. Current evidence suggests that, similar to RA, both class I and class II genes play a role in susceptibility to disease, although to different alleles. For example, the class I alleles *HLA-A2* and *HLA-B27* and the class II genes *HLA-DRB1* and *HLA-DP* have all been associated with various

subtypes of JIA. In the future it will be fascinating to discover the HLA types and amino acids that drive the risk of disease in more homogeneous subtypes of JIA and whether they mirror the adult diseases (e.g., AS and psoriasis). There is a large subgroup that are clinically distinct from adult forms of inflammatory arthritis, including the early onset, anti-nuclear antigen $(ANA)^+$ subgroup, and again, it will be interesting to explore the overlap with SLE, as well as to understand the key differences between subgroups.

Outside the *HLA* region, GWAS and immunochip studies have led to identification of 17 genes robustly confirmed to be associated with JIA susceptibility.[67] Knowledge of these genes has already provided insights into the pathogenesis of disease. For example, JIA shares many loci with the adult form of RA, including association at the *PTPN22*, *IL2*, and *IL2RA* genes. However, the *IL2* pathway appears to be more prevalent in the juvenile form of disease, with *IL2* and *IL2RA* conferring larger effect sizes than in RA, and other genes in the pathway also being associated, including *PTPN2* and *RUNX1*. The *IL2* pathway is enriched in persons with type 1 diabetes, a disease that appears to share more genetic loci with JIA than it does with RA.

## Psoriatic Arthritis

Genealogical and family studies suggest that the genetic contribution to PsA is greater than that to psoriasis alone. Family studies have estimated the sibling recurrence risk to be in the region of 40, yet many of the susceptibility loci identified are shared with psoriasis. This finding is hardly surprising because most patients with PsA will have psoriasis, and thus far, GWAS studies have been performed using only modest sample sizes of patients with PsA. Early GWAS studies identified the *TRAF3IP2* gene as being associated with PsA, with an effect size larger than psoriasis.[68] However, association at this locus was also observed in samples from patients with psoriasis, some of whom may also have had PsA, illustrating the difficulty of proving the existence of PsA-specific loci. In a follow-up study investigating 17 loci that did not reach genome-wide levels of significance in the original GWAS, association with the *RUNX3* gene was confirmed in both PsA and psoriasis.[69] The largest genetic study to date used the immunochip array to test nearly 2000 patients with PsA and 9000 control subjects.[69a] Eight loci showed confirmed evidence for association at genome-wide significance levels, seven of which have previously been reported to be associated with psoriasis (*HLA-C*, *TRAF3IP2*, *IL12B*, *IL23R*, *IL23A-STAT2*, *TNIP1*, and *TYK2*). However, the SNPs predisposing to disease appear to be different between psoriasis and PsA for at least one locus, *IL23R*. Furthermore, two PsA-specific loci were identified: one at chromosome 5q31 and the other in the MHC (*HLA-B27*). The association with the MHC is complex, with three major associations detected with PsA: the classic psoriasis-associated *HLA-C*0602; HLA-B27*, and *HLA-A*02*. An independent study investigating just the MHC locus also found that the HLA-B association differentiated subjects with PsA and subjects with psoriasis alone. In that study, the amino acid at position 45, found on the *HLA-B27* allele, was associated with PsA exclusively.[70] It is likely that as sample sizes improve for PsA, further loci will be identified, and it will be possible to dissect the shared and distinct loci for these overlapping diseases. This dissection is important because it would potentially pave the way to screen patients with psoriasis for the risk of the development of PsA.

## Ankylosing Spondylitis

Family studies indicate that AS has a substantial genetic component, with a sibling recurrence risk of 9.2% compared with 0.1% to 0.4% in the general population.[71] Based on these figures, the heritability has been estimated to exceed 95%.

The strongest genetic susceptibility factor for AS is carriage of the *HLA-B27* allele. In white populations, more than 90% of patients with AS carry *HLA-B27*, in contrast to approximately 8% of healthy persons, giving estimated RR values of 50 to 100 or higher.[72] However, AS will develop in only 2% of people who are *HLA-B27* positive, indicating the presence of other genetic, environmental, and stochastic risks. The consistency of the association with AS across most ethnic groups lends support to the contention that the *HLA-B27* alleles are directly involved in disease pathogenesis.[73,74] *HLA-B27* is also associated with reactive arthritis and with the arthritis seen in the context of inflammatory bowel disease. The serologic specificity of HLA-B27 actually encompasses many distinct class I HLA alleles. These alleles differ from one another at a number of amino acid positions, most of which involve amino acid substitutions in and around the peptide-binding pocket. This fact leads naturally to the question of whether differences exist among these B27 alleles in terms of disease association. Most data indicate that this is not the case, although some exceptions may exist in some populations.[73] These exceptions may provide clues to the role of the HLA-B27 molecule in pathogenesis. Overall, however, it appears that most of the structural differences among the *B27* alleles do not affect disease risk.

Outside the *HLA* gene region, recent genetic studies have identified 25 additional risk loci to date.[75] These findings have highlighted several important insights into underlying disease pathways and mechanisms. First, the association of several aminopeptidase genes (*ERAP1*, *ERAP2*, *LNPEP*, and *NPEPPS*) has reinforced the importance of antigen presentation in AS pathogenesis because these genes encode proteins that trim peptides to be presented to HLA molecules. Interestingly, the *ERAP1* association is only found in *HLA-B27*$^+$ persons and was one of the first examples of genetic epistasis; that is, the presence of both *HLA-B27* and *ERAP1* risk variants increased the disease risk multiplicatively.[76] In contrast, *ERAP2* is also associated with *HLA-B27*$^-$ AS. Studies in mice specifically implicate *ERAP1* in viral peptide generation and presentation. Second, there is enrichment of genes involved in the *IL23* pathway, including *IL23R*, *IL-12B*, and *IL27*. The pathway drives the differentiation of $CD4^+$ Th17 cells, which produce IL-17. Encouragingly, early phase clinical trials of biologic drugs targeting the IL-23 and IL-17 signaling pathways have shown promising results in patients with AS. Third, pathways involving T cell differentiation (*EOMES*, *IL7R*, *RUNX3*, *ZMIZ1*, *BACH2*, and *SH2B3*) and G-protein coupled receptors (*GPR35*, *GPR37*, *GPR65*, and *GPR25*) have also been identified. Although the *IL1* gene cluster has

been implicated in some studies, findings have been inconsistent, and trials of an anti–IL-1 biologic drug, anakinra, were not successful for the treatment of AS.[77,78] Finally, there appears to be considerable overlap in the genes predisposing to AS and Crohn's disease. Given that up to 60% of patients with AS have been reported to show histopathologic evidence of gut inflammation and that a pathway comprising genes involved in the defense against pathogens has been identified in Crohn's disease, there is now considerable interest in the role of the gut microbiome in the predisposition to AS.[79]

## Systemic Lupus Erythematosus: Identification of the Interferon Pathway

In 2005, researchers showed that IFN regulatory factor 5 *(IRF5)* was associated with susceptibility to systemic lupus,[80] and they replicated this finding shortly thereafter.[81] This observation was satisfying because activation of IFN pathways is clearly central to the pathogenesis of lupus and related disorders.[82] Since the time of these original observations, it has become apparent that multiple genes in IFN pathways are involved in lupus susceptibility.[83] IFN has emerged as a potential drug target, and there is renewed appreciation and interest in the role of IFN regulation in the immune response generally.[84] The involvement of multiple genes in IFN pathways as risk factors for autoimmune diseases provides important support for continuing biologic studies in this field, as well as the potential for new insights into the details of how this pathway is regulated.

Researchers into the genetic contribution to SLE have pioneered the way in determining critical biologic pathways that lead to disease. These breakthroughs have arisen from the usual GWAS and immunochip routes but have also incorporated robust findings from family and single-gene studies and transethnic studies. Monogenetic disorders, such as Aicardi-Goutières syndrome, share many of the phenotypes of the complex genetic form of SLE.[85] Using family linkage approaches, key genes and biologic pathways have been uncovered in these studies, including *TREX1* (which is important in IFN-α production), complement deficiency, and Fas ligand (which is implicated in apoptosis).

Putting these discoveries together with the data generated from case-control association studies has led to the provisional identification of four key pathways involved in SLE susceptibility. These pathways are the type 1 interferon pathway, as exemplified by the association of *IRF5*, *IFIH1*, and *TYK2*; the NF-κB pathway (*TNFAIP3* and *IRAK1*); B and T cell signaling pathways (*PTPN22* and *BLK*); and apoptosis (*ITGAM* and *FCGR2A*).[86] These groundbreaking findings are the first steps toward a stratified medicine approach whereby patients with SLE with a B cell signal–driven disease, for example, could be grouped together and may well respond better to a specific therapeutic approach.

## Osteoarthritis

Osteoarthritis (OA) is the most common musculoskeletal disorder, but because of its high prevalence in so-called "healthy control populations," identifying the genes underlying this disease has been very challenging because large numbers of "controls" will go onto experience OA in the future. Furthermore, different patterns of clinical joint involvement are apparent and were described before the era of genetics. Genetic studies have confirmed that different genes seem to underlie these phenotypic subgroups. GWAS have now confirmed association to 11 genomic intervals at genome-wide thresholds[87] (Table 21-7).

**TABLE 21-7** Summary of Genes/Loci Associated with Osteoarthritis at Genome-wide Levels of Significance as of August 2014

| Gene/Chromosome Locus | Joint | Population |
|---|---|---|
| *GDF5* | Knee | European and Asian |
| *7q22* | Knee | European |
| *COL6A4P1* | Knee | Asian |
| *HLA-BTNL2* | Knee | Asian |
| *MCF2L* | Knee and hip | European |
| *GLN3* | Knee and hip | European |
| *ASTN2* | Hip total joint replacement | European (women) |
| *CHST11* | Hip total joint replacement | European |
| *FILIP1/SENP6* | Hip | European |
| *KLHL42* | Hip | European |
| *DOT1L* | Hip | European (men) |

It should be noted that, as in other GWAS, rather than being able to pinpoint a single gene, it is often a chromosomal region that is found to be associated with the disease. The locus is often named according to the gene closest to the strongest association signal or the most likely candidate based on existing knowledge. However, in most cases, the gene that is conferring risk has not yet been conclusively identified. The most thoroughly investigated locus to date is the *GDF5* locus mapping to chromosome 20. Interestingly, this is one of two regions (*GDF5* and *DOT1L*) that are also inversely associated with height (i.e., the risk allele for OA is associated with being smaller[88]). The risk alleles for *GDF5* are absent in the African population, are common in European populations, and show positive selection in East Asians, suggesting that they may confer a survival advantage, but what that survival advantage is remains unclear. It has been suggested that the WNT signaling pathway plays a key role in OA, and genetic studies provide some evidence to support this suggestion. For example, the *GDF5* gene has been found to reduce matrix metalloproteinase 13 expression via the WNT pathway[89]; the 7q22 region contains the *HBP1* gene, which has been reported to suppress WNT signaling,[90] whereas the *DOT1L* gene encodes a methyltransferase that acts on the same pathway.[91] However, further functional studies will be required to confirm the importance of the pathway in OA etiopathogenesis. It is evident that many more genes have yet to be identified for OA, and this endeavor will require further GWAS in larger sample sizes.

## Clinical Translation

GWAS is only a starting point in understanding the genetic basis of musculoskeletal diseases. The technique often identifies a region of interest for which further fine-mapping or resequencing studies are required to refine the peak of association and identify a group of likely causal variants. Bioinformatics analysis can be used to prioritize the likely candidate gene in a region and the likely causal variant, but ultimately, experimental verification and functional studies are required to prove causation. Only once the causal genes have been defined can reliable pathway analysis be undertaken. At the time of the writing of this chapter, the causal gene within an associated locus has been unequivocally identified in only a few cases.[63] However, genetic studies could potentially be used to inform clinical practice in other ways, as outlined.

### Identification of Drug Targets: Lessons from Rheumatoid Arthritis Genetics

Three of the genes identified in RA GWAS are the targets for drugs that are highly effective in the management of disease activity: abatacept is an analogue of the molecule encoded by the *CTLA4* gene; tocilizumab is a biologic drug that perfectly mimics the action of the RA-associated variant within the *IL6R* gene; and tofacitinib acts on the JAK/STAT pathway in which the RA-associated gene, *TYK2*, is crucially involved. Indeed, drug targets have been reported to be enriched in the largest analysis of RA genetic studies, which identified more than 100 RA susceptibility genes.[55] Therefore, genetic studies can highlight novel targets or pathways for drug development. Supported by genetic data, several drugs targeting the IL-17 and IL-23 pathways in PsA and AS are in early phase clinical trials, along with drugs targeting the IFN pathway in SLE.

### Prognosis

It is recognized that huge variability exists in the course of musculoskeletal diseases, but few reliable predictors of outcome have yet been identified. In RA, the presence of ACPA as measured by ACPA antibody status is more predictive of the development of erosions than the presence of rheumatoid factor at baseline but does not completely explain the variance in outcome.[92] However, it is expected that disease severity will be genetically determined, and a family study in early RA has provided support for this expectation.[93]

A number of other non-HLA genes or genetic loci have been investigated in terms of whether they can predict severity. The most consistent evidence for association with severity is for *HLA-DRB1* SE alleles. The *TRAF1/C5* locus has also been associated with joint erosions in multiple populations[94-97] but was not replicated in a subsequent study.[98] Two studies have reported association of the *IL4R* gene with outcome.[99,100] An additional two studies have reported association of the *IL2RA* gene with erosions.[101,102] However, findings for many have not been replicated in all studies, and none of the variants provides sufficient discrimination to be of clinical utility alone.

### Treatment Response

Several biologic therapies are available, particularly for RA, that target specific pathways. However, for each drug or drug class, fewer than half of the patients treated achieve remission. Currently, drugs are used on a trial-and-error basis, often in the order they came to market rather than on any scientific rationale. It would be tempting to speculate that remission rates would be improved if the initial biologic used was selected to target the major pathway mediating inflammation in individual patients, which is the concept of precision medicine. The prerequisite is to define the pathways involved in individuals. Currently this approach is limited because, at most associated loci, the gene responsible is not known. As previously explained, gene names are often assigned to a locus based on biologic plausibility or because they are the closest gene to the most associated variant in a region. However, numerous examples exist of this assumption having been proved wrong. For example, rs12740374, an SNP strongly associated with cholesterol levels, is found within the gene *CELSR2*, but it has been convincingly shown to confer its functional effect on cholesterol levels by changing the expression of *SORT1* in the liver, a gene separated from *CELSR2* on the chromosome by 2 other genes (*PSRC1* and *MYBPHL*).[103] If the wrong gene is assigned to a locus, then downstream pathway analysis to define subgroups of patients by the predominant pathway involved may be catastrophically compromised, and treatment response rates based on such groupings are unlikely to be improved. Therefore, precision medicine with use of genetic biomarkers is only likely to become a reality once the genes responsible for the association signal in a region are identified.

In the meantime, efforts are ongoing to assign patients to strata according to their known treatment response to drugs, which is known as stratified medicine. In several countries, longitudinal cohort studies are under way in which genetic data are being generated from patients who have received a drug, usually a biologic drug, and whose response to therapy has been recorded using standardized definitions of response. In Europe and, increasingly, in the United States, the outcome measure used is usually the change in disease activity score across 28 joints (DAS28) or European League against Rheumatism (EULAR) response criteria, which are based on the DAS28.[104,105] Studies to identify genetic predictors of response lag behind those of studies of susceptibility for several reasons. First, the difference between responders to a drug and nonresponders is more subtle than between patients with a disease and control subjects without a disease. Issues about how moderate responders are classified can complicate the phenotype definition, for example. Furthermore, the outcome measure itself is a composite score comprising both subjective measures (e.g., tender joint count and patient global health score) and objective measures (e.g., swollen joint count, erythrocyte sedimentation rate, or C-reactive protein). Second, the genetic studies performed thus far have been in modest sample sizes. For example, one of the first GWAS of anti-TNF response was performed in 566 patient samples, encompassing good, bad, and moderate responders, and thus study power has been a major limitation.[106] Third, biologics acting on the same pathway have been grouped, as in the

study described, but evidence shows that etanercept has different properties than monoclonal anti-TNF drugs. Thus progress in stratified medicine has been slow, but international collaboration recently led to the first moderately sized GWAS, which identified the *CD84* gene as approaching genome-wide significance levels for association with response to etanercept.[107] Independent studies from Denmark and Spain have replicated association to the *PDE3A-SLCO1C1* and, in a combined analysis, the association statistic exceeded genomewide thresholds.[108] The *PTPRC* gene has been associated with anti-TNF response by two independent groups, but a combined analysis still does not meet thresholds to claim confirmed association.[109,110] Efforts are continuing, but we can already conclude that there is no major genetic determinant of anti-TNF response of an effect size similar to that of the *HLA* region with RA. Instead, response is likely to be mediated by a large number of genes, each with a small individual effect, and signatures of response might be more realistic.

## IDENTIFICATION OF HIGH-RISK GROUPS

Because of the low prevalence of many rheumatic diseases (with the exception of OA) and the low effect sizes for most of the risk loci identified, it is unlikely that population screening to identify groups at risk of disease will ever be feasible. Even for age-related macular degeneration, for which large effect sizes at a modest number of genes have been found, the sensitivity and specificity of the testing means that population screening will probably not be cost-effective. However, genetic testing may be of more use in an already high-risk group, for example, in RA, those with a family history of disease, or those who are ACPA$^+$. It may be more feasible for PsA, because patients with psoriasis are already at higher risk for developing PsA than the general population. This could pave the way for preventative therapies for high-risk individuals in the future, and several cohort studies are under way to identify other factors that may increase risk further.

CHAPTER 22

# Epigenetics of Rheumatic Diseases

Amr H. Sawalha

**KEY POINTS**

- Epigenetic mechanisms include DNA methylation, histone modifications, and noncoding ribonucleic acid regulation. Collectively, epigenetic mechanisms determine chromatin architecture, accessibility of genetic loci to transcriptional machinery, and gene expression levels.
- Epigenetic changes are cell-type specific, and epigenetic regulation plays an important role in regulating the normal immune response, such as T cell differentiation.
- Epigenetic alterations are increasingly recognized as playing an important role in the pathogenesis of a growing number of rheumatic diseases.
- Epigenome-wide studies in rheumatology have focused primarily on DNA methylation changes and have resulted in the identification of novel target genes and pathogenic mechanisms in immune-mediated diseases.
- The epigenome is dynamic, allowing for the development of novel biomarkers for disease activity, specific disease manifestations, and response to treatment.
- Some epigenetic changes reflect the effect of environmental triggers that cause disease in a genetically susceptible host. An integrated "omics" approach would help to better understand disease pathogenesis in rheumatology.

Epigenetics refers to changes in gene regulation without changes in the DNA sequence. These changes are often described as "heritable," indicating a relative stability of epigenetic changes during cell division. Three main epigenetic mechanisms are thought to operate in concert to regulate chromatin architecture, thereby controlling the accessibility of regulatory regions within the genome to transcriptional machinery. Therefore, epigenetic changes are often described as "silencing" or "activating," indicating the net effect of a given epigenetic change on gene expression (transcription). DNA methylation, histone modifications, and regulatory RNAs, such as microRNAs, have evolved in mammalian systems to provide a complex array of epigenetic changes that determine specific chromatin architecture in any given genetic locus to regulate gene expression. These epigenetic mechanisms are essential during development and tissue differentiation, as well as in dictating the repertoire of genes expressed by the various cell types and tissues. Every nucleated cell contains the same repertoire of the human genome, yet each cell type maintains a specific assortment of expressed genes that is necessary for its function, while the rest of the genome is silenced. This silencing is achieved by epigenetic changes and the relative presence or absence of transcription factors. Indeed, two elements must co-exist for any gene to be expressed in any cell type: chromatin accessibility and appropriate transcription factors. If either is absent in a particular gene locus, that gene cannot be expressed.

## EPIGENETIC REGULATION

The genetic material (DNA) that carries the genetic code within nucleotide bases is tightly packed within the nucleus with histone proteins to form the chromatin. The chromatin basic units are known as nucleosomes, which consist of ~147 base pairs (bp) of DNA wrapped twice around a core protein octamer consisting of two of each histone protein, H2A, H2B, H3, and H4.[1] This architectural arrangement serves two main purposes; first, it allows for the genomic material to be compacted in such a way that it fits within the tight space of the nucleus, and second, it provides an avenue for regulating gene expression through epigenetic modifications, as will be described later in more detail.

DNA methylation is the most studied epigenetic mechanism and is considered the cornerstone of epigenetic regulation. DNA methylation refers to the addition of a methyl group (–CH3) to the fifth carbon of cytosine rings.[2] This reaction is mediated by a group of enzymes called DNA methyltransferases (DNMTs). DNMT3A and 3B are considered de novo DNMTs because they determine and establish DNA methylation patterns in utero.[3] DNMT1 is the "maintenance" DNMT because it maintains DNA methylation patterns throughout cell division ex utero.[4-6] Although this is a general rule, naturally some exceptions exist, and some redundancies within the DNMTs as a group in specific situations and cell types have been described. The methyl group in DNA methylation reactions is derived from S-adenosyl-methionine, which gets converted to S-adenosyl-homocysteine after donating a methyl group (Figure 22-1). Therefore, dietary changes that affect micronutrient levels in S-adenosyl-methionine metabolism can potentially alter DNA methylation and provide a link between metabolism and gene expression patterns.[7] DNA methylation most often occurs in cytosine residues within cytosine-guanosine (CG) dinucleotides. However, non-CG methylation, which is very frequent in plants, has been recently described in mammalian cells. Non-CG methylation typically occurs in cytosines within CA or CT dinucleotides and is generally restricted to embryonic stem cells and developing brain tissue.[8,9]

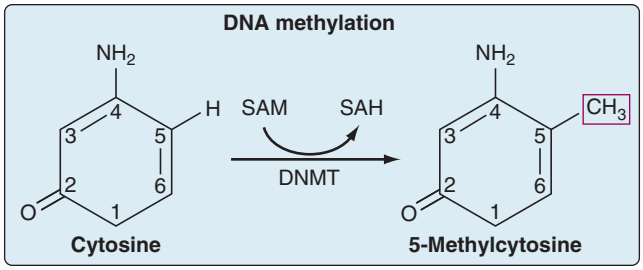

**Figure 22-1** DNA methylation refers to the addition of a methyl group to the fifth carbon in cytosine rings. Most DNA methylation occurs in cytosine residues within cytosine-guanosine (CG) dinucleotides, although non-CG cytosine methylation has also been recently described. DNA methylation is mediated by DNA methyltransferase enzymes (DNMTs) that use S-adenosyl-methionine as the methyl group donor. SAM, S-adenosyl-methionine; SAH, S-adenosyl-homocysteine.

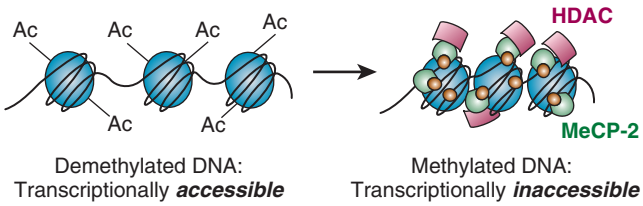

**Figure 22-2** DNA methylation represses gene expression. Transcriptionally accessible regions in the genome are generally characterized by DNA demethylated and histone tails acetylation. When DNA gets methylated *(red circles)*, it recruits a methyl-binding domain including proteins such as MeCP-2 *(green)*, which in turn recruits histone deacetylase (HDAC) 1 and 2. HDACs cleave off the acetyl group from histone tails, increasing the charge attraction between DNA and histone cores and thereby increasing chromatin compaction and reducing accessibility to transcription factors. The presence of methyl-binding proteins and HDACs also physically hinders transcription factor binding.

DNA methylation in promoter or regulatory sequences within the genome generally silences gene expression. Demethylation or hypomethylation, by contrast, is associated with active transcription. DNA methylation inhibits gene expression by several mechanisms. One important mechanism is inducing histone deacetylation (Figure 22-2). Methylated DNA recruits methyl-binding, domain-containing proteins, such as methyl-cytosine-phosphatidyl-guanine (CpG)-binding protein 2 (MeCP-2). MeCP-2 recruits and binds histone deacetylases (HDAC1 and 2), and the latter cleave off the acetyl groups from acetylated histone tails, thereby increasing the charge attraction between the histone core and DNA strands and inducing a compact chromatin architecture that becomes inaccessible to the transcriptional machinery, resulting in gene silencing.[10,11]

A number of histone tail modifications play a role in epigenetic regulation. As previously mentioned, histone acetylation (primarily of histones H3 and H4) is associated with transcriptional accessibility and active gene expression. Deacetylation of H3 and H4 silences gene expression. Other histone tail modifications have variable effects on gene expression, depending on the specific modification and the specific location of these modifications within histone proteins. The details of these histone changes are beyond the scope of this chapter, but generally they include acetylation, methylation, phosphorylation, ubiquitination, and others.[12] Increasingly, the complexity of the effects of histone changes on chromatin architecture has been recognized. Mapping chromatin modifications across the genome and in multiple cell types and tissues has resulted in a better understanding of chromatin regulation and architecture, as has been recently demonstrated by the ENCODE project.[13]

The importance of gene regulation by noncoding (nc) RNA (such as microRNAs) has been recognized by a recent Nobel Prize in Medicine and Physiology awarded in 2006 to Andrew Fire and Craig Mello. MicroRNAs are small RNA molecules of generally between 19 to 25 nucleotides that regulate the expression of target genes by binding to regulatory elements within their specific target genes, such as the 3′ untranslated regions (3′-UTR).[14] Our knowledge of the different types of regulatory RNAs, their biology and regulatory potential and function, and the specific target regions and genes they regulate is constantly evolving. In this chapter, we will focus on microRNAs as the most studied regulatory RNA in the context of autoimmune and rheumatic conditions.

The timeline for some of the major epigenetic discoveries and progress is outlined in Figure 22-3.

## EPIGENETICS AND THE IMMUNE RESPONSE

Epigenetic mechanisms are critically involved in the regulation of multiple aspects of the normal immune response.[15] We will discuss only a few examples in this chapter to demonstrate two important points: the role of epigenetic changes in the normal functions of immune cells that are thought to be key in the development of autoimmune and inflammatory diseases, and the utmost importance of examining specific cell types (not a mixture of cells) in epigenetic studies of immune-mediated diseases.

T cell activation is associated with a rapid production of interleukin (IL)-2, resulting in a feedback loop of further expression of the high-affinity IL-2 receptor α (IL-2Rα or CD25) and more IL-2 production (autocrine mechanism). This rapid and efficient IL-2 production is associated with a robust and rapid demethylation of the *IL2* promoter sequence. Indeed, this demethylation starts within minutes after T cell stimulation and therefore is clearly independent of cell cycle or cell division.[16,17] This characterization was in opposition to the dogma that DNA demethylation is passive and cell cycle dependent. In subsequent years we witnessed the characterization of DNA demethylation as an active process mediated by the ten-eleven translocation (TET) system and through the generation of 5-hydroxymethylcytosine and 5-caboxylmethylcytocine, both of which are intermediates in a demethylation reaction during the conversion of methylated to unmethylated cytosine residues.[18,19]

The differentiation of naïve $CD4^+$ T cells to T helper (Th)1 and Th2 effector cells is accompanied by essential and locus-specific epigenetic changes.[15] In naïve $CD4^+$ T cells, the Th1 locus *(IFNG)* and the Th2 locus (*IL4*, *5*, and *13* common locus control region) are inaccessible for transcription because the DNA is methylated and histone tails in these two loci are deacetylated, resulting in compact chromatin that is transcriptionally repressive. Upon Th1 differentiation, the Th1 locus *(IFNG)* gets demethylated and histone tails become acetylated, leading

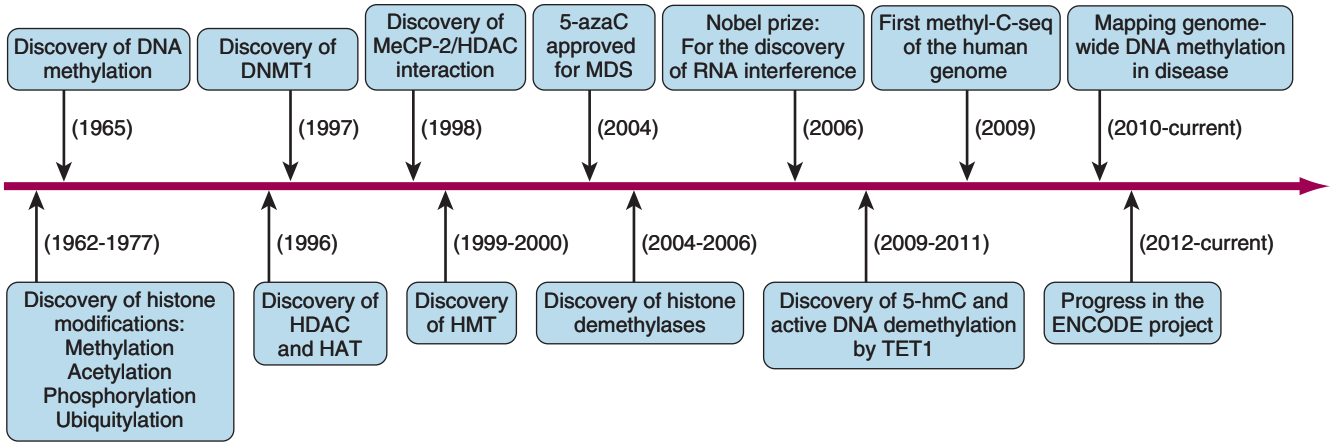

**Figure 22-3** The timeline for key discoveries and progress in epigenetics. DNMT1, DNA methyltransferase 1; HDAC, histone deacetylase; HAT, histone acetyltransferase; HMT, histone methyltransferase; MDS, myelodysplastic syndrome; TET1, ten-eleven translocation methylcytosine dioxygenase 1; ENCODE, Encyclopedia of DNA Elements.

to a locus-specific chromatin accessibility and the production of the key Th1 cytokine interferon (IFN)-γ. At the same time, the Th2 locus control region becomes even more methylated compared with naïve $CD4^+$ T cells to ensure no production of Th2 cytokines.[20,21] The exact opposite happens in the Th2 locus control region and the Th1 *IFNG* locus upon naïve $CD4^+$ T cell differentiation into Th2 effector cells.[22-24] Importantly, these locus-specific methylation changes are maintained upon memory Th1 and Th2 cell generation to ensure a rapid clonal T cell response upon re-exposure to the same pathogen. Indeed, the 2 to 3 days it generally takes for an initial Th1 or Th2 immune response is largely the time needed for the aforementioned locus-specific methylation changes to happen, and this explains why a second-exposure response from memory T cells is much faster.[25] The development of IL-17–producing Th17 cells is similarly accompanied by chromatin remodeling in the *IL17A* and *17F* loci.[26] Regulatory T cells (Tregs) demethylate the *FOXP3* genetic locus, resulting in the ability to produce FOXP3, a key transcription factor in the immune-regulatory function of these cells.[27] Therefore, locus-specific epigenetic changes play a critical role in the differentiation of T cells into specific subsets with a specific cellular function and cytokine-producing capacity.

## EPIGENETICS IN RHEUMATIC DISEASES

### Systemic Lupus Erythematosus

The etiology of systemic lupus erythematosus (SLE) is not completely understood. A strong and growing body of literature supports a role for epigenetic changes in the pathogenesis of SLE.[28-30] Most of these studies are focused on T cells, because demethylated T cells are sufficient to induce SLE in animal models. Initial studies in the epigenetics of SLE, and in rheumatology in general, originated from Dr. Bruce Richardson's work at the University of Michigan. As a result of this work, and subsequent work by other investigators, epigenetics is now in the center of the current paradigm of SLE pathogenesis. Indeed, epigenetics provides a link between environmental triggers and genetic susceptibility in autoimmune diseases.

#### DNA Methylation Regulation and Candidate Gene Studies in Systemic Lupus Erythematosus T Cells

Initial studies demonstrated that procainamide and hydralazine cause drug-induced SLE by demethylating T cells, thereby resulting in T cell autoreactivity. Both procainamide and hydralazine inhibit the activity of the maintenance DNA methyltransferase DNMT1. Procainamide directly inhibits DNMT1 in T cells, whereas hydralazine inhibits MEK/ERK signaling, which regulates and mediates DNMT1 expression.[31,32] $CD4^+$ T cells treated with procainamide or hydralazine, the DNA methylation inhibitor 5-azacytidine, or MEK/ERK pathway inhibitors overexpress messenger (m)RNA and proteins encoded by methylation sensitive genes (such as CD11a, CD70, perforin, CD40L, and killer cell immunoglobulin-like receptor [KIR] family) and become autoreactive, capable of killing autologous macrophages and stimulating B cell immunoglobulin production in vitro.[28] In vivo experiments, using adoptive transfer of similarly treated demethylated T cells into syngeneic mice, cause autoantibody production and an SLE-like disease.[28] T cells isolated from patients with SLE demonstrate reduced MEK/ERK signaling, reduced DNMT1 expression and activity, and demethylation of the promoter sequences, resulting in overexpression of CD11a, CD70, perforin, CD40L, and KIRs, similar to 5-azaC–treated T cells.[28] Therefore, T cells from patients with SLE resemble normal T cells treated with MEK/ERK pathway inhibitors or DNA methylation inhibitors. The extent of the MEK/ERK signaling defect and reduction in DNMT1 expression in SLE T cells is proportional to disease activity, with T cells isolated from patients with active SLE showing more extensive demethylation compared with patients with inactive disease.[33]

To further provide a proof of principle that reduced MEK/ERK signaling in T cells can result in T cell demethylation and SLE, rather than the alternative possibility that

the observed MEK/ERK signaling defect in SLE is the result of and not causal to the disease, a transgenic mouse model with an induced T cell MEK/ERK signaling defect was generated.[34] These mice demonstrated that inducing a defect in the MEK/ERK signaling pathway resulted in reduced DNMT1 expression, demethylation of methylation sensitive genes, and overexpression of these same genes, similar to T cells isolated from patients with SLE.[34,35] Further, this mouse model developed anti–double-stranded (ds)DNA antibodies and a T cell interferon expression signature, reminiscent of the interferon signature in patients with SLE.[34] When they have a genetic background permissive to autoimmunity, these mice also developed clinical SLE-like disease such as glomerulonephritis.[35] Taken together, inducing a DNA methylation defect in T cells is sufficient to cause autoimmunity in subjects with an autoimmune-resistant genetic background and a clinical SLE-like phenotype in the presence of a genetic background that is permissive to autoimmunity. This finding is similar to the finding that, in humans taking hydralazine (which is an MEK/ERK inhibitor), autoantibodies develop in the majority of patients and a clinical SLE-like disease develops in only a small fraction of patients, presumably those with a genetic background for SLE. This observation provides a basis for genetic-epigenetic interaction in the pathogenesis of SLE; other evidence for this interaction is discussed in later sections.

In subsequent studies, investigators mapped the origin of the MEK/ERK signaling defect in SLE T cells that causes the observed DNA methylation defect to an upstream signaling defect in protein kinase C (PKC)-δ.[36] Interestingly, oxidative stress such as oxygen free radical species can induce a defect in PKC-δ signaling similar to that observed in SLE T cells, resulting in T cell DNA demethylation.[37,38] These data provide a link between environmental triggers of oxidative stress, such as infections, and autoimmunity in the susceptible host. Infections are known to induce flares in patients with SLE, and this reaction might be mediated at least partly by increased oxidative stress, resulting in T cell demethylation. In fact, mitochondrial dysfunction resulting in increased production of reactive oxygen species and reduced levels of the antioxidant glutathione have been reported in SLE T cells.[39] Increased oxidative stress in SLE T cells also results in activation of the mammalian target of rapamycin (mTOR) signaling pathway, which also inhibits DNMT1.[39] Treatment of patients who have SLE with the antioxidant and glutathione precursor N-acetylcysteine blocked mTOR in T cells and improved disease activity.[40]

Recent data have also provided evidence for additional mechanisms that play a role in inducing the DNA methylation defect in SLE T cells. For example, protein phosphatase 2A (PP2A), which is involved in multiple cellular processes, including proliferation and activation, is overexpressed in SLE T cells. Increased PP2A expression and activity has been linked to reduced IL-2 production, which is characteristic of SLE T cells.[41] Recent evidence suggests that increased PP2A might be inducing a DNA methylation defect in SLE T cells by causing an MEK/ERK signaling defect, thereby reducing DNMT1 expression. Indeed, suppressing PP2A in SLE T cells enhanced MEK/ERK signaling, increased *DNMT1* mRNA expression, and reduced the expression of methylation-sensitive genes such as *CD70*.[42] Further, increased PP2A induces epigenetic changes in the *IL17* locus, enhancing IL-17 production from SLE T cells. PP2A catalytic subunit (PP2Ac) transgenic mice develop an IL-17–dependent glomerulonephritis.[43]

The growth arrest and DNA damage–induced 45α (GADD45α), which is involved in DNA repair and DNA demethylation, is overexpressed at the mRNA and protein levels in SLE $CD4^+$ T cells.[44] Inhibiting GADD45α in SLE $CD4^+$ T cells using siRNA resulted in increased methylation of *ITGAL* (encoding CD11a) and *CD70 (TNFSF7)* promoter regions and reduced *ITGAL* and *CD70* mRNA expression, reduced T cell proliferation, and reduced T cell autoreactivity as measured by B cell co-stimulation.[44]

Other contributing factors to the DNA methylation defect and overexpression of methylation-sensitive genes in SLE $CD4^+$ T cells include downregulation of regulatory factor X1 (RFX1). RFX1 recruits DNMT1 and HDAC1 and suppresses CD11a and CD70 expression, and underexpression of RFX1 is associated with demethylation and increased expression in CD11a and CD70 in SLE $CD4^+$ T cells.[45]

### Genome-wide DNA Methylation Studies in Systemic Lupus Erythematosus T Cells

Genome-wide DNA methylation studies have been performed recently in SLE. These studies provide an unbiased view of the DNA methylome and have identified a number of novel differentially methylated genetic loci that might be important in the pathogenesis of this disease. Using a group of twins discordant for SLE, Javierre and colleagues[46] investigated SLE-associated DNA methylation changes in ~1500 CpG sites in peripheral blood leukocytes. This first genome-wide study of DNA methylation in SLE was followed shortly by another study examining ~27,000 CpG sites in $CD4^+$ T cells from patients with SLE compared with healthy age-, sex-, and ethnicity-matched control subjects.[47] Several differentially methylated regions were identified in $CD4^+$ T cells, including hypomethylation of *CD9* (T cell co-stimulatory molecule), *MMP9* (matrix metalloproteinase involved in autoimmunity), *PDGFRA* (platelet-derived growth factor receptor-α precursor), *CASP1* (caspase 1), and IFN-regulated genes such as *IFI44L* and *BST2*.[47]

Subsequent work by Coit and colleagues[48] identified genome-wide DNA methylation changes across more than 485,000 methylation sites in naïve $CD4^+$ T cells in SLE. This study included a discovery and a replication cohort to robustly identify and replicate DNA methylation changes, coupled with gene expression profiling in a subset of the same samples. This study demonstrated for the first time a robust and consistent hypomethylation in IFN signature genes in SLE, which precedes gene expression.[48] Therefore, it appears that naïve $CD4^+$ T cells in patients with SLE are poised at the epigenetic level to produce type I IFN-regulated genes even before T cell activation (Figure 22-4). These data provided a mechanistic explanation for the previously reported increased type I IFN sensitivity in SLE peripheral blood mononuclear cells (PBMCs) and adds yet another pathogenic role for abnormal DNA methylation in the pathogenesis of SLE.[48] Hypomethylation of IFN-regulated genes was subsequently replicated and extended to B cells and monocytes in SLE.[49] More recently,

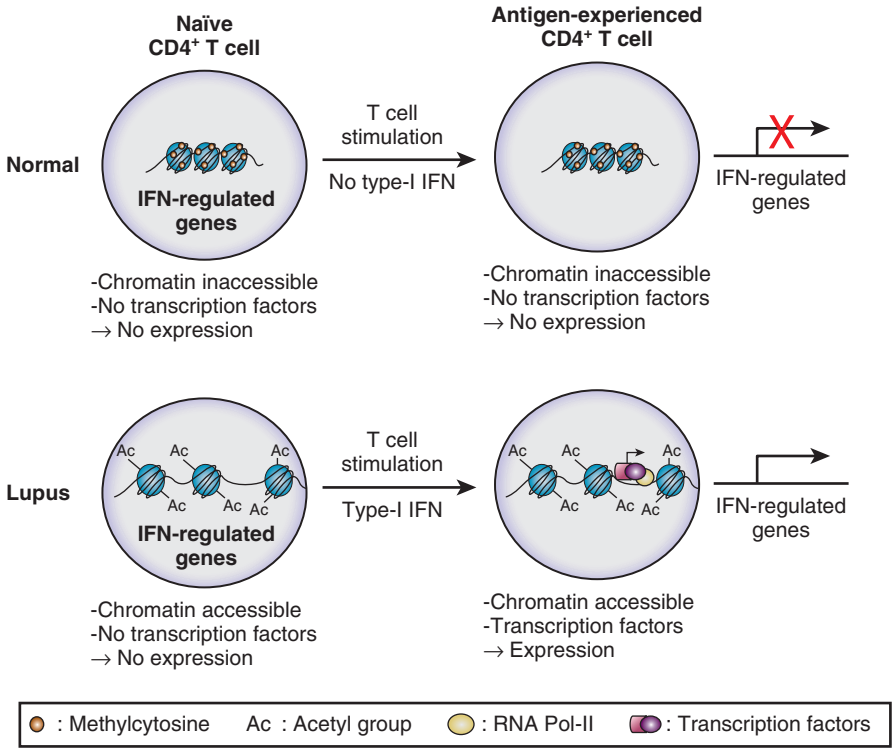

**Figure 22-4** Interferon (IFN)-regulated genes are epigenetically "poised" in naïve CD4+ T cells in systemic lupus erythematosus (SLE), because abnormal DNA demethylation exists in SLE T cells before activation. A model whereby interferon-regulated genes are epigenetically poised to respond to type I IFN upon T cell activation in SLE is proposed. These data provide evidence for an epigenetic architecture favoring—and providing an explanation for—type I interferon hyper-responsiveness in SLE T cells.

a genome-wide DNA methylation study coupled with transcriptome and microRNome analysis in SLE CD4+ T cells identified additional DNA methylation changes in SLE, such as the differential methylation and overexpression of novel target genes, including *NLRP2* (inflammasome component gene), *CD300LB* (a pro-inflammatory nonclassical activating receptor of the immunoglobulin superfamily), and *S1PR3* (a pro-inflammatory G protein–coupled receptor).[50] Further, this study localized some methylation changes that are specific to clinical disease subsets in SLE, such as kidney and skin disease.[50]

## Genetic–Epigenetic Interaction in Systemic Lupus Erythematosus

MeCP-2, encoded by *MECP2*, is a key transcriptional regulator that is intimately involved in DNA methylation–mediated transcriptional repression. Numerous studies have identified and replicated the genetic association between *MECP2* and SLE, suggesting that genetic variants within *MECP2* are associated with increased risk for SLE.[51-53] This was the first link suggesting a potential role for genetic-epigenetic interaction in the pathogenesis of SLE. Subsequent studies indicated that the SLE-risk variant in *MECP2* is associated with increased mRNA expression of one *MECP2* transcript variant in stimulated but not unstimulated T cells and that mice overexpressing human MeCP-2 develop anti-nuclear antibodies and a gene expression profile characterized by an IFN signature in activated CD4+ T cells.[54] Importantly, the DNA methylome of stimulated T cells from healthy persons carrying the SLE-risk variant in *MECP2* reveal hypomethylation of several IFN-regulated genes.[54]

Genetic-epigenetic interaction plays a role in the severity of flares in patients with SLE. A positive correlation exists between genetic risk to the T cell DNA methylation ratio and SLE disease activity in patients with SLE.[55] Moreover, male patients with SLE require a higher genetic risk and/or lower T cell DNA methylation to achieve an SLE flare of equal severity to that of women.[55] Genetic risk alone or T cell DNA methylation alone could not explain the difference between men and women in SLE flare severity. These data provide further evidence for genetic–epigenetic interaction in SLE and suggest that although genetic risk is relatively stable over time, dynamic changes in T cell DNA methylation might play an important role in SLE flares, in interaction with the genetic susceptibility for SLE.

## Histone Modifications in Systemic Lupus Erythematosus

Histone acetylation status is a product of the balance between histone acetyltransferases and histone deacetylases. As the name implies, the former increases histone acetylation, whereas the latter leads to its reduction. As previously discussed, histone acetylation/deacetylation determines chromatin accessibility and is influenced by the DNA methylation status (Figure 22-2). One of the earliest reports related to histone changes in SLE suggested that histone deacetylase inhibitors can abrogate SLE-like disease

in murine models. Histone deacetylase inhibitors downregulated the production of several cytokines including IFN-γ, IL-12, IL-10, and IL-6 in MRL/lpr mice. Further, mice treated with histone deacetylase inhibitors showed a global increase in histone H3 and H4 acetylation as expected, and more importantly, demonstrated significant improvement in renal diseases.[56] Similarly, NZB/W SLE-prone mice treated with a histone deacetylase inhibitor also showed improvement of renal disease, reduction in Th17 cells, and increased Tregs and acetylation of the Treg key transcription factor gene *FoxP3*. Therefore, histone deacetylase inhibitors might provide therapeutic effectiveness in SLE by altering T cell subsets and reducing pathogenic Th17 cells while increasing Tregs.[57]

Gene-specific studies in human disease demonstrated the importance of histone changes in suppressing IL-2 and inducing IL-17 production in SLE T cells.[58] In SLE monocytes, the *TNF* (encoding TNF) locus is more acetylated compared with normal control monocytes, and this hyperacetylation is associated with increased *TNF* mRNA expression.[59]

At a genome-wide level, although histone changes in SLE have not been as extensively studied as DNA methylation, $CD4^+$ T cells from patients with SLE demonstrate reduced global H3 and H4 acetylation.[60] This finding is consistent with a beneficial effect of HDAC inhibitors in SLE mice as previously discussed. Mapping histone H4 acetylation in SLE monocytes suggested that the majority of hyperacetylated loci are potentially regulated by type I IFNs.[61]

### MicroRNAs and the Pathogenesis of Systemic Lupus Erythematosus

Differential expression of microRNAs has been reported in multiple cell types in patients with SLE.[14,62] Because microRNA expression is involved in the regulation of multiple aspects of the normal immune response, it is not surprising that changes in the microRNA milieu can be associated with autoimmunity. Some of the dysregulated microRNAs in SLE tie in specific and credible pathogenic aspects of the disease and therefore can be targeted as novel therapeutic targets in the future. Overexpression of several microRNAs in SLE $CD4^+$ T cells contributes to the DNA methylation defect described in previous sections. The expression of microRNAs miR-126 and miR-148a is increased in SLE $CD4^+$ T cells, and they both directly target and inhibit *DNMT1*.[63,64] MiR-21, which is also upregulated in SLE $CD4^+$ T cells, inhibits DNA methylation by targeting *RASGRP1*, an upstream component in the MEK/ERK signaling pathway that regulates *DNMT1* expression.[64] These data demonstrate the interaction between two distinct epigenetic mechanisms in SLE, DNA methylation, and microRNA regulation.

An example of downregulated microRNAs in SLE is miR-31. Downregulation of miR-31, which directly targets and represses RhoA, contributes to impaired IL-2 production in SLE T cells.[65] Another downregulated microRNA in SLE is miR-146a, which targets several IFN-related genes, such as *IRAK1*, *TRAF6*, *IRF5*, and *STAT1*.[66,67] Downregulation of miR-146a results in increased activation of type I IFN, a characteristic pathogenic feature of SLE.[67]

Of interest, a genetic association between the *miR146a* locus and SLE has been described, and the risk variant in this locus is associated with downregulation of miR-146a.[68] This is another example of genetic-epigenetic interaction in SLE, whereby a genetic variant might contribute to SLE pathogenesis by affecting the expression of an epigenetic affecter molecule. Another such example is the genetic polymorphism in the 3′UTR region in *TLR7* in patients with SLE, which is located in a binding site for miR-3148, suggesting that this genetic variant in *TLR7* might induce pathogenicity by altering the epigenetic regulation of *TLR7*. Indeed, the SLE-associated variant in this locus is associated with increased TLR7 mRNA and protein expression, and the mRNA expression levels of *TLR7* in SLE and normal PBMCs was inversely correlated with miR-3148 expression.[69]

## Rheumatoid Arthritis

Fibroblast-like synoviocytes (FLS) are thought to play an important role in rheumatoid arthritis (RA). FLS are activated and produce a number of pro-inflammatory cytokines in joints of patients with RA. Further, this pro-inflammatory phenotype is associated with increased production of specific matrix metalloproteinases into the synovial fluid, leading to joint destruction. Earlier studies showed that FLS in patients with RA are characterized by global DNA hypomethylation, and as a result, express L1 retrotransposable elements; this global hypomethylation is presumably due to decreased expression of DNMT1.[70] Treating normal FLS with DNA methylation inhibitors results in phenotypic changes resembling activated FLS from patients with RA, as well as in overexpression of several gene products, including miR-203, which is increased in RA FLS and correlates with levels of IL-6 production.[71] Multiple other microRNAs are also overexpressed in RA FLS, such as miR-155, which is similarly upregulated in RA PBMC and synovial macrophages.[72,73] MiR-155 is a pro-inflammatory microRNA because miR-155–deficient mice are resistant to collagen-induced arthritis.[73] MiR-223 is overexpressed in the synovium, in peripheral blood naïve $CD4^+$ T cells, and in the serum in patients with RA, and its expression levels in the serum correlate with disease activity in treatment-naïve early RA.[74-76]

The overall role of miR-223 as a therapeutic target in RA remains controversial. Overexpression of miR-223 suppresses osteoclastogenesis in vitro, suggesting a potential beneficial therapeutic effect of miR-223 overexpression[75]; however, suppressing miR-223 in vivo ameliorates arthritis, bone erosions, and osteoclastogenesis in mice with collagen-induced arthritis,[77] suggesting a pathogenic effect of this same microRNA molecule. Of interest, miR-146a, which is downregulated in SLE peripheral blood leukocytes, is overexpressed in PBMCs and FLS from patients with RA,[72,78] although the exact role of miR-146a in RA has not been clearly elucidated.

Global reduction in T cell DNA methylation levels and DNA methyltransferase activity has been described in patients with RA, but to a lesser extent than has been observed in active SLE.[79] Further, a genome-wide DNA methylation study in peripheral blood leukocytes from twin pairs discordant for RA failed to show DNA methylation

differences, contrary to SLE in the same study.[46] A demethylated "senescent" $CD4^+$ T cell subset ($CD4^+CD28^-$ T cells) is expanded in RA and overexpresses a number of proteins encoded by methylation-sensitive genes such as CD70, perforin, and KIRs.[80] How much and what causal role this T cell subset plays in RA is currently not clear, but it is unlikely to be specific for RA because this T cell subset is expanded in multiple chronic inflammatory diseases. It is interesting, however, that this $CD4^+CD28^-$ T cell subset is found in atherosclerotic lesions and is implicated in plaque development and rupture,[81,82] because RA is an independent risk factor for atherosclerotic cardiovascular disease.

Recent genome-wide DNA methylation studies in persons with RA have focused on elucidating DNA methylation differences between FLS from patients compared with control subjects who have osteoarthritis (OA). In one study examining genomic DNA isolated from FLS of six patients with RA and five control subjects with OA, a number of differentially methylated genes that could play a role in RA were revealed, including hypomethylation of *CASP1*, *STAT3*, *MMP20*, *TRAF2*, and *MEFV*, among others.[83] Hypomethylation was enriched in pathways related to cell migration, adhesion, and extra-cellular matrix interactions. Interestingly, several CG sites in the TNF encoding gene *(TNF)* were hypermethylated in RA FLS.[83] Another study examined and integrated changes in the DNA methylome with microRNA expression and gene expression analysis in FLS from six patients with RA and six patients with OA.[84] This study identified differential methylation in novel genes in RA, including hypomethylation in *IL6R*, *CD74*, *TNFAIP8*, and *CAPN8* and hypermethylation in *DPP4*, *CCR6*, and *HOXC4*, among others. These data also demonstrated inverse correlation between DNA methylation levels and gene expression in more than 200 genes in RA. Importantly, several novel dysregulated microRNAs were revealed in this study, such as miR-503, -551b, -550, and -625.[84]

## Primary Sjögren's Syndrome

Primary Sjögren's syndrome (pSS) is a systemic autoimmune disease characterized by lymphocytic infiltration of exocrine glands, primarily salivary and lacrimal glands, resulting in dryness of the eyes and mouth. Global DNA methylation levels in labial salivary gland epithelial cells from patients with pSS is decreased, and this reduction correlates with lower DNMT1 levels and increased expression of the demethylating co-factor GADD45α.[85] The presence and extent of the DNA methylation defect in salivary gland epithelial cells in pSS correlates with the presence of B cell infiltrates, which was confirmed in vitro using salivary gland epithelial cell/B cell co-culture.[85] However, no global reduction in peripheral blood B cell or T cell methylation levels were detected.[85] Gene-specific DNA methylation studies in peripheral blood $CD4^+$ T cells in pSS revealed demethylation and overexpression of the co-stimulatory molecule CD70, similar to what had been previously observed in patients with SLE.[86] In contrast, *FOXP3* is hypermethylation and transcriptionally repressed in $CD4^+$ T cells from pSS, which is consistent with the Treg functional defect reported in pSS.[87]

The only genome-wide DNA methylation study published to date in pSS examined DNA methylation differences in more than 485,000 methylation sites in naïve $CD4^+$ T cells compared with age-, sex-, and ethnicity-matched control subjects.[88] This study identified 753 differentially methylated sites, with the majority being hypomethylated in pSS compared with control subjects. Several hypomethylated genes of interest in pSS include *CD247*, *TNFRSF25*, *PTPRC*, *GSTM1*, and *PDCD1*. Several IFN-regulated genes were also hypomethylated, consistent with an IFN signature in pSS.[88] *LTA*, which encodes lymphotoxin-α (LTα, or TNF-β) and promotes IFN production, was also hypomethylated in naïve $CD4^+$ T cells in pSS. LTα is overexpressed in the serum and salivary glands from patients with pSS, and a clinical trial to block the lymphotoxin pathway as a therapeutic option in persons with pSS is under way. An interesting group of solute carrier protein genes was also differentially methylated in naïve $CD4^+$ T cells from pSS.[88]

## Systemic Sclerosis

Systemic sclerosis (scleroderma) is an autoimmune disease characterized by immune activation, vasculopathy including microvascular endothelial cell dysfunction, and excessive collagen production and fibrosis of the skin and internal organs. Epigenetic studies in scleroderma have therefore focused on fibroblasts, microvascular endothelial cells, and $CD4^+$ T cells.[89,90]

Fibroblasts from patients with scleroderma underexpress FLi-1, a negative regulator of collagen synthesis,[91] which is hypermethylated in fibroblasts from patients with scleroderma compared with control subjects.[92] Further, H3 and H4 acetylation levels are reduced in the *FLI1* promoter region, probably contributing to its transcriptional repression. Treating scleroderma fibroblasts with DNA methylation inhibitors combined with histone deacetylase inhibitors increases *FLI1* expression and restores collagen production to levels comparable with that of normal fibroblasts.[92] These data suggest that hypermethylation and hypoacetylation of *FLI1* in scleroderma fibroblasts might be playing a role in the pathogenesis of this profibrotic disease. Indeed, DNMT1 protein levels and the protein levels of the histone deacetylases HDAC1 and HDAC6 were shown to be elevated in scleroderma fibroblasts,[92] which could explain the hypermethylated and hypoacetylated repressive status of *FLI1*. Recent data suggest that the Wnt pathway signaling antagonists genes *DKK1* and *SFRP1* are underexpressed and silenced by hypermethylation in scleroderma fibroblasts.[93] Importantly, inhibiting DNMT1 reduced canonical Wnt pathway signaling in scleroderma fibroblasts and reduced bleomycin-induced fibrosis in mice.[93] Multiple microRNAs have been shown to be dysregulated in scleroderma fibroblasts compared with control subjects, with several targeting components in transforming growth factor (TGF)-β signaling. For example, miR-21 and -146 are overexpressed, putatively targeting SMAD4 and SMAD7, respectively.[90]

A recent genome-wide DNA methylation study in skin fibroblasts from patients with diffuse and limited scleroderma identified a large number of differentially methylated genes between patients and age-, sex-, and

ethnicity-matched healthy control subjects.[94] It is interesting that despite previous reports showing increased DNMT1 expression in scleroderma fibroblasts, most DNA methylation changes observed using this genome-wide unbiased approach were hypomethylation changes in patients compared with healthy control subjects. This report revealed methylation changes that are common between diffuse and limited disease, and also subset-specific DNA methylation changes. Hypomethylated genes in both diffuse and limited scleroderma included collagen genes such as *COL4A2* and *COL23A1*, *PAX9*, *TNXB*, *ITGA9*, *ADAM12*, and the RUNX transcription family members *RUNX1*, *RUNX2*, and *RUNX3*. Increased mRNA expression levels in several of these hypomethylated genes was also demonstrated in the same study.[94]

Studies in microvascular endothelial cells in scleroderma demonstrated increased methylation in *BMPR2* encoding bone morphogenic protein receptor II, which plays a role in endothelial cell resistance to apoptosis. BMPR2 is underexpressed in microvascular endothelial cells from patients with scleroderma, and in vitro treatment with DNA methylation/histone deacetylase inhibitors restores expression levels of BMPR2 to levels similar to those of healthy control subjects.[95]

$CD4^+$ T cells in patients with scleroderma express less DNMT1 compared with healthy control subjects[96] and overexpress proteins encoded by methylation-sensitive genes such as *CD70* and *CD40L*, and the promoter sequences of these genes are hypomethylated.[97,98] This observation is very similar to a previous observation in SLE $CD4^+$ T cells.

## Behçet's Disease

Behçet's disease is an immune-mediated inflammatory disease characterized by recurrent oral-genital ulcers, inflammatory eye disease, skin involvement, central nervous system involvement, and recurrent thrombosis. The cause of Behçet's disease is not completely understood, but unsurprisingly, genetic and environmental factors play a role in the pathogenesis of the disease. A recent genome-wide DNA methylation study of Behçet's disease shed light on the epigenetic architecture of $CD4^+$ T cells and monocytes in patients with Behçet's disease who have active untreated disease compared with healthy age-, sex-, and ethnicity-matched control subjects.[99] The study identified key differentially methylated loci and pathways across the genome in Behçet's disease that can be targeted for the development of novel therapeutic interventions in the future. Several regulatory and structural cytoskeletal components showed consistent DNA methylation change in both $CD4^+$ T cells and in monocytes in this disease. Differentially methylated genes in Behçet's disease include *RAC1*, *RGS14*, *FSCN2*, among others. Moreover, these epigenetic changes were dynamic, because the study showed clear evidence for reversibility of DNA methylation changes when the same patients were examined at a subsequent time after disease remission.[99] Therefore, this study of Behçet's disease provides evidence that DNA methylation does change throughout the course of the disease and that some of these epigenetically altered loci can be explored as novel disease biomarkers and therapeutic targets.

## Osteoarthritis

Several recent genome-wide DNA methylation studies in articular cartilage tissue have been reported and suggest that epigenetic profiling can identify novel candidate genes and disease aspects, therapeutic targets, disease subsets, and epigenetic biomarkers for disease severity in OA.[100-102] In a study examining DNA methylation in ~27,000 CG sites in cartilage tissue from patients with OA in the knee compared with healthy control subjects, 91 differentially methylated CG sites were identified between the two groups. Importantly, genome-wide methylation data and gene expression profiling identified a cluster of patients with OA who had a more "inflammatory" disease.[100] These data suggested that epigenetic and transcriptional profiling can identify disease subsets in OA, which could help target specific therapeutic options in a more individualized manner in the future.

Another study examined DNA methylation changes in hip joint OA across more than 485,000 methylation sites and used a unique approach comparing eroded with noneroded cartilage tissue from the same joint.[101] This approach eliminates any confounding effect from genetic variants across the groups. Remarkably, ~40% of genetic risk variants previously reported in OA showed evidence of differential methylation in this study, suggesting that genetic–epigenetic interaction might play a role in the pathogenesis of OA and that genetic or epigenetic alteration in these same genes are associated with OA risk. The study identified a total of 550 differentially methylated genes in OA, with more than two thirds of them hypomethylated. Bioinformatic analysis to identify common regulating factors among these differentially methylated genes identified TGF-β1 and several microRNAs such as miR-128, -27a, and -9. Importantly, this study showed correlation between DNA methylation in 20 CG sites and histologic severity scores in OA.[101]

# FUTURE DIRECTIONS

Epigenetic dysregulation has been increasingly recognized as a major factor involved in the pathogenesis of rheumatic diseases. In the past few years we have witnessed a growing interest in studying epigenetic differences between patients with various autoimmune, inflammatory, and non-inflammatory rheumatic conditions and healthy control subjects. The availability of unbiased genome-wide approaches has broadened our knowledge and allowed the identification of novel epigenetically altered genetic loci that can help us better understand disease pathogenesis and identify novel targets for therapy.

With this plethora of epigenetic and epigenomic studies in rheumatology, several issues need to be kept in mind. Epigenetic changes are cell specific, and therefore, moving forward, it is of utmost importance that very specific cell subsets should be examined to accurately capture epigenetic differences between patients and control subjects that represent genuine disease-associated differences, rather than the effect of differences in cellular constituents or cell activation status between patients and control subjects. Adequately powered studies to address the clinical heterogeneity of the disease of interest, careful phenotyping of patients,

and careful selection of matched healthy control subjects should be emphasized.

The dynamic nature of epigenetic changes would allow for the development of novel disease biomarkers. Indeed, in rheumatology there is a paucity of reliable biomarkers. Future studies would focus and expand on disease subset–specific epigenetic changes. We hope to answer questions such as what specific DNA methylation changes could predict nephritis in patients with SLE and what specific epigenetic changes could predict the development of lymphoma in patients with Sjögren's syndrome or severe lung involvement in patients with scleroderma. Some of the epigenetic changes that we need to discover and validate in future studies can also help us assess disease activity, predict disease flares, or determine what treatment option to use in an increasingly personalized medicine approach. One way to achieve this goal is to conduct longitudinal epigenetic studies in rheumatology—that is, to follow the same group of patients over time rather than using the more common cross-sectional approach. A longitudinal approach would also help address the question of "cause" versus "effect" in the epigenomic changes we associate with the various diseases. Ideally, a longitudinal approach that would entail following up and collecting biological samples from a group of persons before disease develops would be most informative in dissecting the issue of causality.

Future studies in epigenomics in rheumatology should also more comprehensively address genetic-epigenetic interaction, as well as the interaction between environmental triggers of disease, epigenomic changes, and the disease genetic background. Studies have already been initiated to examine allele-specific epigenetic changes to understand how some genetic variants that are associated with diseases induce risk. These efforts will need to be expanded to a genome-wide level. An integrated "omics" approach that includes the genome, epigenome, transcriptome, and exosome (environmental exposures) would be very informative to comprehensively understand and better treat rheumatic diseases in the very near future.

CHAPTER 23

# Complement System

Leendert A. Trouw

**KEY POINTS**

- The complement system is a delicately balanced protein activation cascade that includes several regulators that prevent unwanted and disproportional complement activation under physiologic conditions.
- In several forms of arthritis, complement is activated in the joints.
- Deposition of autoantibodies represents an important trigger for complement activation.
- Measuring complement levels and activation fragments is useful in the diagnosis and follow-up of patients who have systemic lupus erythematosus, but it is not equally validated in many other rheumatic conditions.
- Complement proteins may play additional roles outside the traditional complement activation cascades.

The time when complement was mainly considered an antibacterial defense mechanism via the pore-forming membrane attack complex is long gone. In addition to great progress in understanding the molecular functioning of complement proteins, substantial changes have occurred in the possibilities of modulating complement activation therapeutically in patients. Therefore the goal of this chapter is to provide rheumatologists with a fresh view on the physiologic and pathologic role of the complement system in the context of rheumatic diseases. Furthermore, a large array of tests is currently available to monitor complement levels and complement activation, but the interpretation of these results is not always straightforward. This chapter will provide guidance in the interpretation of laboratory test results in the context of the several rheumatic conditions.

## FUNCTIONS OF THE COMPLEMENT SYSTEM

The complement system was discovered more than a century ago and until relatively recently was considered to be a mechanism only involved in the defense against infections. In the experiments that led to the identification of complement, scientists learned that a substance with the capacity to kill bacteria was present in the cell-free fraction of blood. This substance had properties that were very different from the properties of antibodies. The substance was heat labile, unstable, and present in all individuals, whereas antibodies were heat stabile and required prior exposure to or immunization with, for example, certain bacteria. Sets of mixing experiments finally revealed that for the observed lytic effects, both antibodies and this substance were required. Because this substance was considered to "complement" the action of the antibodies to mediate lysis and host protection, the name *complement* was coined.[1]

Given that the identification of complement was based on lysis experiments and that for many years the laboratory readouts for complement activity were based on lysis assays, an important role for lysis as an effector mechanism of complement was implied. Today it is understood that although complement-mediated lysis does take place in vivo and may contribute to tissue damage, defense against infections is not dependent on this mechanism, indicating that complement has several other effector mechanisms that may overall have more impact than the simple insertion of lytic pores. Opsonization and generalized immune activation via anaphylatoxins represent more important mechanisms used by complement to mediate host protection in concert with the remainder of the innate and adaptive immune system.[1]

By now it is clear that complement plays a role in innate immune defense and instruction of adaptive immune responses. In addition, it is important in clearance of waste, such as apoptotic and necrotic cells, as well as immune complexes, prions, and amyloid-β aggregates. Finally, complement is involved in other cascades and processes such as coagulation, tissue repair, angiogenesis, placentation, and tumor cell survival. Unraveling the contribution of complement activation to a clinical condition is often difficult, because a similar deposition of C3b could either contribute to tissue damage or stimulate regeneration. The molecule C1q can contribute to immune complex–mediated damage in persons with systemic lupus erythematosus (SLE), whereas deficiency of C1q is the strongest genetic risk factor for the development of SLE. Collectively, these examples illustrate that the interpretation of laboratory results, including the activity levels of the pathways, the presence of circulating activation fragments, or tissue depositions, is not always straightforward. Although our understanding of the overall role of complement in rheumatic diseases is far from complete, this chapter provides an overview of current insights.

## TERMINOLOGY USED TO DESCRIBE COMPLEMENT AND ITS ACTIVATION FRAGMENTS

For scientists and clinicians who do not work with complement on an everyday basis, the nomenclature used to

describe the different complement factors, especially the convertases and the activation products, may appear confusing. However, some logic can be found in the nomenclature. Under the auspices of the International Complement Society (ICS) and the European Complement Network (ECN), a standing committee dedicated to enhancing the use of standardized terminology for both old and newly discovered proteins recently completed a much-needed update.[2] Complement proteins are mostly indicated by a capital letter followed by a number and a lowercase letter suffix (e.g., C5a and C5b). The molecular part designated with the letter "a" indicates the smaller molecular fragment, whereas the designation "b" indicates the larger fragment. The only exception to this rule is C2, for which the large cleavage fragment is indicated by the letter "a" and the small part by the letter "b." The Nomenclature Committee for Complement reported that no consensus has yet been reached to change this aberrant usage of "a" and "b" for C2, and therefore in this chapter it is referred to in the original manner.[2]

The three activation pathways of complement—that is, the classical pathway, the lectin pathway, and the alternative pathway—converge to cleave and activate the central component C3 (Figure 23-1). After cleavage of C3, all three pathways use the same terminal pathway that generates the membrane attack complex (MAC; Figure 23-1).

The nine proteins of the first pathway to be discovered, the classical pathway, are designated with an uppercase letter C, followed by a number (e.g., C2). Although most of these numbers are in a logical numeric order, one exception exists—C4—which is cleaved together with C2 and before C3. The components of the lectin pathway are largely similar to those of the classical pathway, but the proteins unique to the lectin pathway do not have a similar logical nomenclature. For the alternative pathway, however, most of the proteins involved are indicated by the word "factor" followed by an uppercase letter (e.g., factor B). Enzymatically active component or protein complexes are often indicated by a bar above the name (e.g., $\overline{C3Bb}$). After inactivation by complement inhibitors, several complement proteins can no longer participate in further complement activation and are indicated with a lowercase prefix "i," indicating "inactivated" (e.g., iC3b).

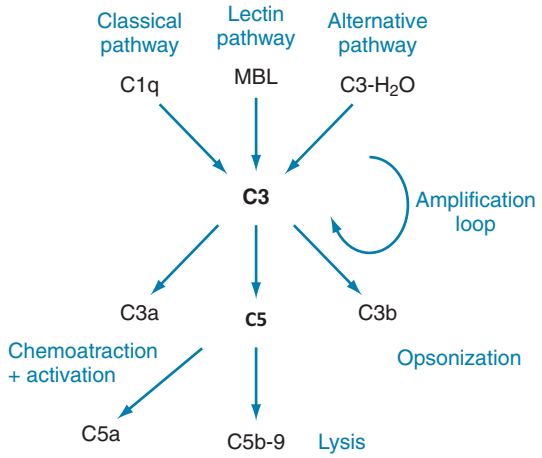

**Figure 23-1** Schematic overview of the different complement activation pathways. Key recognition molecules for each of the pathways are highlighted, as well as the key components and activation products. MBL, Mannan-binding lectin.

## ACTIVATION PATHWAYS

Traditionally, three different pathways of complement activation are distinguished: the classical pathway, the lectin pathway, and the alternative pathway (see Figure 23-1). In addition to these three pathways, several "shortcuts" collectively referred to as extrinsic complement activation also have been described and will be discussed only briefly.

The classical pathway becomes activated when its recognition molecule C1q binds to one of its ligands. Whereas initially mainly surface-bound immunoglobulin (Ig)M and complexed IgG were thought to be the main ligands for C1q, the list of relevant ligands has now been expanded and includes, among others, C-reactive protein (CRP), DNA, microbial components, and apoptotic and necrotic cells.[3] C1q is initially part of the C1 complex, which also comprises two C1r and two C1s molecules. After the binding of C1q to its ligands, a consecutive activation of C1r and C1s takes place.[4] The activated form of C1s now has the capacity to cleave C4 to C4a and C4b, exposing a hidden thioether residue that leads to the immediate covalent attachment of C4b on surfaces close to the place where C1q was binding to its ligands. This quick and covalent binding ensures that opsonization takes place at the right place.

Next, activated C1s also cleaves C4b-bound C2, generating C2a and C2b. The result of this cleavage is the formation of the classical pathway C3-convertase C4b2a. As the name implies, the C3 convertase is an enzymatic protein complex that has the capacity to cleave C3 into its active fragments C3a (an anaphylatoxin) and C3b (an opsonin), which, like C4b, bind instantly and covalently to nearby surfaces. C3 is considered to be the central component of complement activation because it is at this point that the three activation pathways converge to follow the same terminal pathway of complement activation, leading to the formation of the MAC (see Figure 23-1).

The lectin pathway is similar to the classical pathway, except for the fact that it uses different recognition molecules (mannan-binding lectin [MBL] and ficolins) and different serine proteases (the MBL-associated serine proteases [MASPs]; Figure 23-1). Most importantly, the ligands that are recognized by the lectin pathway are different and mainly comprise carbohydrate patterns. After binding of MBL, MASP-2 will cleave both C4 and C2, generating exactly the same C3 convertase as in the classical pathway.

The alternative pathway is truly different from the other two pathways and serves two purposes. It is an important activation pathway in its own right, using a tick-over mechanism, and it also serves as an amplification loop for the classical and alternative pathways. The tick-over mediated activation of the alternative pathway refers to the fact that a small fraction of the circulating C3 is hydrolyzed to $C3_{H2O}$. This hydrolyzed form of C3 exposes a binding site for factor B. After binding, factor B is cleaved by factor D, generating a fluid-phase C3-convertase $C3_{H2O}Bb$ that cleaves native C3 into C3a and C3b. Similar to C4b, this C3b also binds covalently to a surface and serves as the starting point for

the generation of a new C3 convertase, C3bBb. However, on host cells this initial binding of C3b is quickly neutralized by the action of several complement inhibitors, especially factor H, whereas insufficient inhibition of this alternative pathway initiation exists on the surface of foreign cells, resulting in strong deposition of C3b and C3 convertases, thereby making the difference between self and non-self.

Properdin is a molecule that stabilizes the alternative pathway C3 convertase by forming a complex, C3bBbP, which allows a longer half-life. However, properdin is now also thought to serve as a pattern recognition molecule that can localize complement activation to surfaces of pathogens or dead cells by attracting C3b, allowing the formation of the alternative pathway C3 convertase.[5] The amplification function of the alternative pathway is often neglected, but as much as 80% of the C3 deposited during complement activation via the classical or lectin pathway may be the result of the alternative pathway amplification loop.[6] This loop is activated simply by the deposition of C3b, which, independent of the pathway by which it was generated, serves as the starting point for more alternative pathway activation as the alternative pathway C3 convertase is built upon this bound C3b.

The terminal pathway of complement activation represents the common final pathway used by all three routes of complement activation. As more and more C3b fragments are generated by way of either the classical, lectin, or alternative pathway or its amplification loop, the C3 convertases also start to acquire additional C3b molecules, C4b2aC3b and C3bBbC3b. These complexes gain a unique property: they now can serve as C5 convertases that cleave C5 into C5a, a very potent anaphylatoxin, and C5b. C5b interacts with C6 and C7, and this complex becomes attached to the cell surface, followed by interaction with C8. However, it is not until several C9 molecules are inserted into the complex that a pore is actually formed in the cell membrane. This final complex is referred to as the MAC or as C5b9. Insertion of many copies of the MAC can lead to cellular activation, apoptosis, or lysis, depending on the dosage and the cell type involved.

As previously mentioned, other processes have been described that lead to complement activation via mechanisms that differ from the traditional complement pathways. Extrinsic complement activation refers to situations in which complement proteins can be cleaved, and hence activated, via noncomplement proteins such as plasmin, thrombin, elastase, and plasma kallikrein.[7,8] For example, cleavage of C5 by these proteases can yield bioactive C5a.[7,8]

## REGULATION OF COMPLEMENT ACTIVATION

Because the complement system is very aggressive and has the potential to be highly damaging, it is not surprising that the human body is equipped with a large array of complement regulators and inhibitors (Table 23-1). These proteins ensure that complement activation is limited in time and in place to ensure maximal effectiveness in fighting infections and clearing debris while minimizing the collateral damage to healthy host tissue.[9] One other important aspect of efficient regulation is the importance of maintaining sufficient levels of complement fragments so they are available to fight infections. In case of deficiencies of fluid-phase complement inhibitors factor I and factor H, the complement system becomes activated via the alternative pathway and does not stop until all complement is consumed, resulting in a secondary C3 deficiency. Both fluid-phase and membrane-bound complement inhibitors function primarily via a similar mechanism of putting a break on unwanted

**TABLE 23-1** Schematic Overview of the Main Complement Regulators

| Regulators | Alternative Names | Function |
|---|---|---|
| C1-INH | SERPIN1 | Inhibits C1r/s and MASPs |
| sMAP | MAP19 | Binds to MBL, competes with MASPs |
| MAP-1 | MAP44 | Binds to MBL/ficolins; inhibits C4 deposition |
| C4BP | C4b-binding protein | Accelerates decay of LP/CP convertases; cofactor for fI |
| Factor H | CFH | Recognizes self-surfaces; accelerates convertase decay; cofactor for fI |
| FHL-1 | Reconectin, CFHL1 | Accelerates convertase decay; cofactor for fI |
| MCP | CD46 | Membrane bound cofactor for fI |
| DAF | CD55 | Membrane bound accelerator of decay of convertases |
| CD59 | Protectin | Membrane bound protein; binds to C8 and C9; prevents assembly of TCC |
| CFHR-1 | FHR-1 | Recognizes self-surfaces and C5; inhibits C5 cleavage and TCC formation |
| Vitronectin | S-protein | Binds to C5b-9; prevents assembly of TCC |
| Clusterin | Apolipoprotein J; SP-40,40 | Binds to C7-C9; prevents assembly of TCC |
| Carboxypeptidase-N | | Degrades C3a and C5a to their des-Arg forms |

CFHR-1, Complement factor H–related protein 1; DAF, decay-accelerating factor; FHL-1, factor H-like protein 1; fI, factor I; MAP-1, MBL/ficolin associated protein-1; MASP, MBL-associated serine protease; MBL, mannan-binding lectin; MCP, membrane cofactor protein; sMAP, small mannose-binding lectin–associated protein; TCC, terminal complement complex.

complement activation at several levels of the complement cascades: initiation, formation of C3 convertases, and MAC insertion.

Fluid-phase regulators circulate together with all the other complement proteins and prevent complement activation under physiologic conditions (Figure 23-2). C1 esterase (C1-INH) inhibits several enzymes of the classical and lectin pathways: C1r, C1s, and MASPs. One of the main fluid-phase inhibitors is factor H, which can serve both as a decay accelerator (decreasing the half-life of C3 convertases) or as a cofactor for the enzymatic degradation of C3b by factor I.[10] The degrading enzyme factor I is present in the circulation without a known inhibitor but only works to degrade C3b in the presence of a cofactor.[11] Once C3b is bound by, for example, factor H, then factor I comes into action and cleaves C3b to iC3b. The iC3b—that is, inactivated C3b—now can no longer serve as a starting point for the formation of a new C3 convertase, but it can still be recognized by complement receptors. Whereas factor H is the main fluid-phase regulator for the alternative pathway, C4b binding protein (C4BP) serves a similar role, mainly for the classical and lectin pathways.[12] Vitronectin and clusterin are fluid-phase regulators of the insertion of the MAC. Finally, carboxypeptidase-N quickly converts the potent anaphylatoxins C3a and C5a into less active, des-arginated forms.

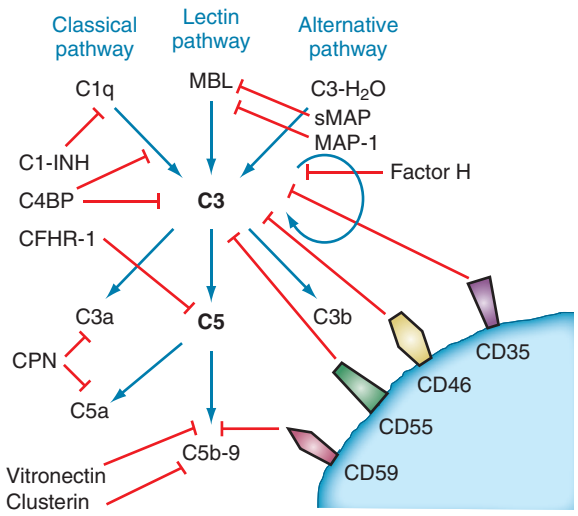

**Figure 23-2** Schematic overview of the different complement inhibitors acting on the complement cascade. Key complement inhibitors are highlighted, together with the parts of the complement cascade that they primarily inhibit. Note that factor I is not indicated; factor I is the enzyme that, together with some of the inhibitors highlighted in the scheme, actually cleaves and inactivates C3b and C4b. CPN, Carboxypeptidase N; MAP-1, MBL/ficolin associated protein-1; MBL, mannan-binding lectin; sMAP, small mannose-binding lectin–associated protein.

Membrane-bound regulators provide important protection against excessive complement attack on host cells (Figure 23-2). Most membrane-bound inhibitors work at the level of the C3 convertases, with the exception of CD59, which inhibits the insertion of the MAC into the cell membranes. Decay-accelerating factor (DAF; CD55) and complement receptor 1 (CR1; CD35) inhibit the action of C3 convertases by reducing their half-life. Membrane-cofactor protein (MCP; CD46) and CR1 serve as cofactors for the action of factor I.

## RECEPTORS FOR COMPLEMENT FRAGMENTS

Even though complement may be best known for its capacity to induce lysis via the MAC, its capacity to activate (immune) cells via complement receptors may actually be much more important in health and disease. Complement receptors (Table 23-2) are present on a large array of immune cells and stromal cells, and the integrated signals lead to a wide variety of biologic processes such as cellular activation, differentiation, and apoptosis. Three types of receptors can be distinguished depending on the type of ligands; C1q,

**TABLE 23-2** Schematic Overview of the Main Complement Receptors

| Receptors | Alternative Names | Function |
|---|---|---|
| CR1 | CD35; C3b/C4b receptor | Binds C3b/iC3b; induces phagocytosis: accelerates decay of convertases; cofactor for fI |
| CR2 | CD21; C3d receptor | Binds iC3b/C3dg/C3d; lowers threshold for B cell stimulation |
| CR3 | CD11b/CD18; Mac-1; integrin αMβ2 | Induces phagocytosis through interaction with iC3b; modulates IL-12 family in APCs |
| CR4 | CD11c/CD18; integrin αXβ2 | Induces phagocytosis through interaction with iC3b |
| C3aR | | Binds C3a; triggers pro/anti-inflammatory signaling |
| C5aR1 | CD88 | Binds C5a; triggers pro-inflammatory signaling |
| C5aR2 | C5L2, GPR77 | Binds C5a (strongly) and C5adesArg (weakly); might bind C3a/C3adesArg; function not fully defined |
| CRIg | Z93Ig, VSIG4 | Induces phagocytosis through interaction with iC3b/C3c; regulatory effect on C5 convertases |
| cC1qR | Calreticulin | Recognizes bound C1q; induces phagocytic signaling through CD91 |
| gC1qR | C1q-binding protein | Recognizes C1q; potential role in phagocytosis and signaling; modulates IL-12 on APCs |
| C1qRp | CD93 + unknown protein | Part of receptor complex that binds C1q and mediates phagocytosis |

APC, Antigen-presenting cell; fI, factor I; IL, interleukin.

Modified from Ricklin D, Hajishengallis G, Yang K, Lambris JD: Complement: a key system for immune surveillance and homeostasis. *Nat Immunol* 11:785–797, 2010.

anaphylatoxins C3a and C5a, and C3 and C4 degradation products.

Several receptors for C1q have been proposed over the years, and most of these molecules actually do bind C1q, but whether they are essential C1q signaling molecules is sometimes debated. It is clear that C1q can have effects on cells, inducing migration and phagocytosis, but the nature or combinations of receptors and binding proteins remains the subject of further studies.

Detection of the anaphylatoxin C3a is mediated via the C3a receptor (C3aR), which is present on mast cells, smooth muscle cells, epithelial and endothelial cells, and cells of the myeloid lineage. Triggering of this receptor can lead to cellular activation, degranulation, and chemotaxis. Signaling via the C3aR may be either pro-inflammatory or anti-inflammatory depending on the context. Detection of anaphylatoxin C5a is mediated via the C5a receptor, C5aR1 (CD88). The C5a receptor is also present on a wide array of immune and nonimmune cells. Triggering results in strong chemotaxis, cellular activation, degranulation, and general immune activation. An alternative C5a receptor also exists, C5aR2 (also known as C5L2), which binds C5a strongly and $C5a_{desarg}$ weakly, and may also interact with $C3a/C3a_{desarg}$.

Cellular recognition of C3 and C4 fragments is mediated via the complement receptors CR1, CR2, CR3, and CR4. Despite their similar names, they have different structures, ligands, expression profiles, and function. CR1 (CD35), which is expressed on several immune cells and on erythrocytes, both enhances phagocytosis by binding to C3b and C4b and serves as a complement regulator that, via factor I, degrades its ligands.[13] CR1 is the only cofactor that allows a second cleavage of iC3b by factor I, generating C3dg. CR1 also serves an important role in transporting complement-opsonized immune complexes via erythrocytes. The C3b/C4b-opsonized immune complexes bind via CR1 to the erythrocytes (immune adherence), which deliver the immune complexes to the liver and spleen, where macrophage-like cells remove the immune complexes. These macrophages do not cleave the immune complexes but, rather, cleave CR1 to release the immune complexes from the erythrocytes.[14] The erythrocytes that re-enter the circulation therefore express less residual CR1 on their surface, a phenomenon sometimes observed in patients with lupus, in whom this immune complex transport and clearance is an important and frequent phenomenon. CR1 on granulocytes and monocytes will induce internalization and degradation of complement-opsonized immune complexes, whereas CR1 on follicular dendritic cells will result in the extra-cellular trapping and presentation of the immune complexes and antigens they contain.

CR2 (CD21) is expressed on B cells and follicular dendritic cells. On the B cells it serves as a co-receptor for signaling through the B cell receptor. The presence of C3d/C3dg on antigens reduces the threshold for B cell activation significantly, resulting in B cell activation and differentiation.[15]

CR3 (CD11b-CD18) and CR4 (CD11c-CD18) are integrin receptors expressed on myeloid cells that both bind iC3b. Both receptors strongly enhance phagocytosis, and CR3 is also involved in shaping the cytokine responses and immune activation in general.

# FUNCTIONS OF THE COMPLEMENT SYSTEM

## Innate Immune Responses

As was previously alluded to, complement plays an important role in the innate defense against invading micro-organisms. Whereas the MAC is responsible for complement-mediated lysis of myriad targets, it is surprising to see that C9 deficiency, which is relatively frequent in Japan, is only associated with infections with *Neisseria*. In contrast, deficiency for C3 is associated with a large array of recurrent infections. Together these findings indicate that the killing of microorganisms does not rely on the MAC, with the exception of *Neisseria*. Apparently, for all other types of infectious organisms, the innate immune defense uses mechanisms in addition to complement-mediated lysis to actually kill the microbes. This process is mediated largely via opsonization with C3b and cellular uptake via complement receptors and activation of immune cells via C3a and C5a. Complement also interacts with other systems of innate immune defense, such as the cellular Toll-like receptors (TLRs).[16] A clear two-directional interaction takes place between those systems; for example, triggering via the C3aR or C5aR/C5L2 may affect the cellular response to lipopolysaccharide (LPS) via TLR4.

Several proteins of the complement system also interact with the cascade of coagulation, collectively enhancing local clotting reactions to prevent the spread of possible pathogens. This bidirectional interaction involves, for example, C5a, which enhances the expression of tissue factor (TF)[17] and stimulates coagulation, whereas in the other direction thrombin has been shown to cleave C5 and generate C5a.[7]

## Clearing Immune Complexes and Apoptotic Material

The important contribution of complement toward clearance of immune complexes and dead cells became apparent from studies of complement-deficient persons. Deficiency of the early components of the classical pathway are associated with development of SLE, with greater risk associated with early components of the complement cascade (C1q–/– > C4–/– > C2–/–). When accumulation of apoptotic cells was also noted in C1q-deficient mice, the waste disposal hypothesis was put forward.[18] C1q can bind to apoptotic and necrotic cells and induce classical pathway activation.[19,20] In the absence of the early classical pathway components, apoptotic cells are not cleared efficiently.[21] Importantly, whereas early complement components bind to apoptotic cells to enhance opsonization and phagocytosis, the binding of fluid-phase inhibitors provides protection against excessive complement attack and lysis.[22]

Clearance of immune complexes is influenced by complement via two mechanisms. The first is the clearance of immune complexes to prevent their tissue precipitation,[23] a process mainly mediated via the classical pathway and transport via erythrocytes. The second mechanism involves solubilization of already existing immune complexes, which is mainly mediated via the alternative pathway. In addition to apoptotic material and immune complexes, many other forms of debris are cleared in ways that involve complement

activation, such as amyloid-β deposits, urate crystals, cholesterol crystals, oxidized lipids, and extra-cellular DNA.

### Regulating Adaptive Immune Responses

The complement system plays an important role in shaping the adaptive immune response. Whereas initially the focus was mainly on B cells and antibody responses, the focus has shifted to the T cell–dendritic cell interface, and now even toward the intra-cellular environment of T cells. C3dg, a degradation product of C3b, serves as a natural adjuvant by providing co-stimulatory signals to B cells via binding to CR2 in the B cell co-receptor complex.[24] In addition to activating B cells, CR2 is also involved in the capture and prolonged presentation of complement-opsonized antigens on follicular dendritic cells.[15] Complement also has an impact on the effector arm of antibodies, not just via the classical pathway, but also by influencing the expression levels of cellular Fcγ receptors. C5aR triggering alters the expression levels of activating and inhibiting Fcγ receptors in such a way that cells are more prone to respond to antibody triggering.[25] Interestingly, Fcγ receptor signaling can enhance synthesis of C5,[26] reinforcing the C5a-Fcγ receptor cross-talk.[25,26]

Direct effects of complement on T cell immunity were concluded from experiments with complement-deficient animals—for example, in the context of transplant rejection.[27] The local production of the anaphylatoxins C3a and C5a in the T cell–dendritic cell synapse highly determines the outcome of these cognate interactions.[28] Expression levels of complement inhibitory molecules such as DAF (CD55) have an impact on the degree of complement activation and hence the degree of dendritic cell and T cell activation. In addition, specific triggering of membrane-bound complement inhibitory molecules such as CD59 and DAF can limit their activation or even skew toward a regulatory T cell phenotype.[29,30]

### Measuring Complement Activation

Many different assays are available to monitor the activity and activation of complement and the antigenic levels of complement proteins. Depending on the clinical question, various assays or different combinations of assays are used. Deposition of activated complement fragments in target organs—for example, the renal glomeruli—provides important clinical information regarding the occurrence of lupus nephritis.

The most commonly used assays to determine the functional activity of complement are based on hemolytic assays for classical pathway and alternative pathway activity (CH50 and AP50). The assay for the classical pathway, CH50, records the ability of serum to lyse sheep erythrocytes that have been opsonized by rabbit IgG antibodies. The assay for the alternative pathway, AP50, records the ability to lyse 50% of rabbit erythrocytes in a buffer that does not allow the classical pathway to be active. The CH50 and AP50 determine the dilution of serum required to achieve this 50% lysis, and as such, these assays provide quantitation of overall activity from the initiation of the pathway to the insertion of the MAC. These assays can be used to screen for deficiencies but can also be used for the evaluation of disease activity and consumption of complement, as, for example, in the context of a flare in patients with SLE. More modern tests now provide platebound variants so that the classical, alternative, and lectin pathways can be screened for activity.[31] These assays are much easier to perform; however, they typically provide no quantitative insight but only a qualitative answer, and hence these assays are more suited to identify deficiencies than to monitor disease activity.

Current activation of complement can be concluded from the measurement of complement activation products—for example, C3a, C5a, C4d, C3d, and C5b-9. Monitoring of the levels of these markers over time allows evaluation of the underlying disease activity. However, in daily practice they are less often used because of the price, availability in routine laboratories, and difficulty of interpretation. As is the case with complement assays in general, the quality of the sample highly determines the reliability of the test. Complement is a heat-sensitive system in which some enzymes will relatively quickly lose their activity, and complement activation fragments may be generated during inappropriate handling of samples.

The antigenic screening for complement proteins C3 and C4 is regularly carried out in most laboratories around the world that perform routine tests, mostly based on nephelometric or turbidimetric assays. These robust assays are often used for the diagnosis and follow-up of patients with SLE in particular.

Several autoantibodies that react with complement proteins have been described.[32] In rheumatology, several autoantibodies such as anti-C1-INH, anti-CR1, and anti-Factor H autoantibodies have been described, but many laboratories that perform routine diagnostic tests offer only the detection of anti-C1q autoantibodies. These anti-C1q autoantibodies, which are relevant especially in the context of lupus nephritis,[33] will be further discussed in the section on SLE.

## COMPLEMENT DEFICIENCY

### Primary Complement Deficiency

Primary deficiencies have been described for nearly all complement proteins. The most common deficiencies are depicted in Table 23-3. Most deficiencies are inherited as autosomal recessive traits, except for the X-linked genes properdin and factor D, which display an autosomal dominant pattern. Almost all of the deficiencies are associated with increased risk for bacterial infections, although for some deficiencies this association only becomes apparent in otherwise immunocompromised hosts. At the time it came as a surprise that for the early classical pathway components—C1q, C4, and C2—their deficiency was highly associated with the development of clinical autoimmunity presenting as SLE-like syndromes.[34] Interestingly, this phenomenon is restricted to SLE, because these deficiencies have not manifested as Sjögren's syndrome, rheumatoid arthritis (RA), or vasculitis. Although SLE develops in a large portion of persons deficient for the early components of the classical pathway, only a very small fraction of all patients with SLE are genetically deficient for one of these early classical pathway components. During flares of their disease, many

**TABLE 23-3** Schematic Overview of the Main Complement Deficiencies

| Protein | Frequency | Disease Association |
|---|---|---|
| C1q | Rare; <100 cases | SLE; glomerulonephritis; infections |
| C1r or C1s | Rare; <50 cases | SLE; glomerulonephritis |
| C2 | 1:20,000 | SLE; infections |
| C4 | Rare; <50 cases | SLE; glomerulonephritis; infections |
| C3 | Rare; <50 cases | Recurrent infections; SLE; glomerulonephritis |
| MBL | Common; 1:10 | Susceptibility to infections |
| Factor D | Rare; <20 cases | Neisserial infections |
| Properdin | Rare; <100 cases | Meningococcal disease |
| C5/6/7/8 | Rare; <100 cases | Usually healthy; some *Neisseria* infections |
| C9 | 1:1000 in Japan | Usually healthy; some *Neisseria* infections |
| C1-INH | 1:50,000 | Hereditary angioedema |

*Estimated frequency in the Caucasian population (with the exception of protein C9).

MBL, Mannan-binding lectin; SLE, systemic lupus erythematosus.

Modified from Sturfelt G, Truedsson L: Complement in the immunopathogenesis of rheumatic disease. *Nat Rev Rheumatol* 8:458–468, 2012.

patients with SLE can display very low levels of these classical pathway components, but this phenomenon is related to immune complex–mediated activation and depletion and is hence a secondary deficiency, as outlined in the next section. C1q deficiency is most strongly associated with SLE (90%), followed by C4 (70%) and C2 (15%) deficiencies. C1q deficiency is rare, with approximately 70 cases currently known,[35] and C1r and C1s deficiency is also rare.[36] Next to increased risk for infections, these patients display a greater than 90% frequency of SLE.

The genes encoding C4 are polymorphic and have undergone ancestral duplication and mutation, giving rise to two genes designated *C4A* (encoding the acidic C4A) and *C4B* (encoding the basic C4B), which are not to be mistaken by the cleavage products C4a and C4b. It has been suggested that functional differences between *C4A* and *C4B* affect the risk for development of SLE, as well as the severity of disease. Homozygous deficiency of C4A, the form of C4 that can interact best with immune complexes, is a susceptibility factor for SLE.[37] In addition to complete genetic deficiency, low copy number variation also has been associated with increased risk for SLE,[38] but this association has not yet been well established.

C2 deficiency is relatively more common, with an estimated frequency of 1:20,000 in white populations.[39] The frequency of SLE in C2-deficient persons is approximately 15%, and the clinical presentation is suggested to be different from the SLE associated with C1q or C4 deficiency.[39]

Deficiencies of other complement factors such as C3, factor B, factor D, and properdin are particularly associated with severe infections.[40] Deficiencies of other factors such as MBL, with an estimated frequency of 1:10 in Caucasians, is associated with infections mainly in otherwise immunocompromised persons.[40] The question of whether MBL deficiency is associated with increased risk for SLE and RA remains controversial, but if any effect exists, it is most likely small. Interestingly, deficiencies of components of the MAC, such as C9, with an estimated frequency of 1:1000 in Japanese populations, do not lead to highly increased risk of infections in general but only to infections with *Neisseria*.[40]

## Secondary Complement Deficiency

Secondary, or acquired, complement deficiency is mainly the result of increased consumption via activation rather than decreased production. Secondary deficiency may occur as a consequence of lack of inhibition, such as in the absence of factor I or factor H, resulting in deregulated activation and depletion of the alternative pathway components, thus leading to a secondary C3 deficiency with an increased risk of infections.[41] However, by far most cases of (partial) secondary deficiency occur because complement activation is consuming more complement proteins than the liver and other tissues can synthesize. Especially in SLE, decreased levels of CH50 and AP50 are detected, which are proportional to decreased circulating levels of C1q, C3, and C4.[42] Hypocomplementemia is a bad sign in persons with SLE because it is related to complement consumption via activation on affected tissues such as the kidneys.[42] Decreased levels of classical pathway proteins are also observed in subsets of patients who have disorders such as mixed cryoglobulinemia and Sjögren's syndrome. In the latter condition, decreased levels of C3 and C4 have been repeatedly identified as markers of unfavorable outcomes, such as lymphoma, severe disease manifestations, and premature death.[43]

# TARGETED COMPLEMENT THERAPEUTICS

For rheumatic diseases, therapeutic intervention focused on complement is aimed either at (1) restoring normal complement function by replenishing deficient components or (2) inhibiting complement activation.

Reconstituting the primary deficiency is a method that has been used for many years. Either purified complement proteins such as MBL and C1-INH or fresh frozen plasma is infused to correct the missing factor. Many complement factors are produced by the liver, and it is worth noting that liver transplantation can reverse certain deficiency states, such as for MBL,[44] although obviously this is not a therapeutic option. However, for C1q, which is mainly produced by cells of hematopoietic origin such as macrophages and dendritic cells,[45] it is possible to reverse the deficiency phenotype completely through hematologic stem cell transplantation. This procedure has been successfully applied, resulting in restoration of circulating C1q levels and diminishment of lupus symptoms.[46]

Despite the important scientific insight that is provided by the association between complement deficiency and rheumatic diseases, it must be noted that this association represents a minute fraction of the patients who have these diseases. In line with what was called the *lupus paradox*, missing complement leads to SLE, but in most patients with SLE, complement contributes to tissue damage, and therefore complement inhibition might be the more appropriate

type of intervention. Several clinically approved interventions currently exist (reviewed in detail elsewhere).[47] One example is soluble CR1 (sCR1). CR1, which is mainly expressed on erythrocytes, mediates complement inhibition by serving as a cofactor for factor I–mediated inactivation of C3b and C4b and as an accelerator of the decay of C3 convertases.[13] Interestingly, the soluble version of CR1 also retains these activities, and modified forms of sCR1 have proven to be effective for the treatment of myocardial infarction.[48] Another main target of intervention is C5—either the C5 molecule itself or the interaction of C5a with the C5a receptor using blocking antibodies or peptides. A humanized antibody to C5 was developed and has been used successfully in the treatment of paroxysmal nocturnal hemoglobinuria (PNH) and atypical hemolytic uremic syndrome (aHUS), and it is currently being tested for several other conditions.[47] Peptides preventing the interaction between C5a and the C5a receptor have been tested in a small study in persons with RA, with no major effects.[49] Currently, blocking antibodies against the C5a receptor are being tested in clinical trials. Complement therapeutics in the context of RA will be discussed in more detail later.

## COMPLEMENT IN RHEUMATIC DISEASES

### Systemic Lupus Erythematosus

The involvement of complement activation in SLE is easily appreciated; not only are affected tissues decorated by activated complement fragments, but serum levels of several key complement components are decreased because of consumption.[42] As mentioned earlier, the lupus paradox makes it difficult to establish if complement plays an essential role in human SLE. On the basis of the tissue deposition of C1q and the heavily decreased levels of circulating C1q during a flare, one would assume that C1q would play an essential role by binding to deposited immune complexes and activating the classical pathway. However, C1q-deficient patients are not protected from lupus. On the contrary, they have a very high chance of developing SLE-like disease, which likely indicates that C1q is involved in two different processes. One process relates to the onset/development of SLE, and the other process relates to the final pathways of tissue destruction that are known to involve, but not totally depend on, complement activation.

SLE is mainly characterized by a breakdown of tolerance against nuclear components, such as double-stranded DNA. Immune complexes are formed between these anti-nuclear antibodies and their antigens, which are released from dead cells. These immune complexes deposit in tissues, where complement activation contributes to tissue damage by the formation of the MAC and the release of pro-inflammatory mediators such as C5a. In addition, the immune complexes stimulate plasmacytoid dendritic cells (pDCs) to produce type I interferons, further stimulating the disease process.[50] Lupus nephritis is a complicated process that is reviewed in detail elsewhere.[51] Substantial clinical information is available for lupus nephritis with regard to the relationship with tissue deposition of complement, decreased circulating levels, and clinical flares of the nephritis.

Circulating levels of C3 and C4 are included in the disease activity index SLEDAI.[52] Measuring cell-bound complement activation fragments, rather than decreased circulating levels of complement, is suggested as possibly being a more sensitive way to analyze complement activation in SLE,[42] but thus far this method has not replaced established assays in laboratories around the world that perform routine testing.

Anti-C1q autoantibodies can be detected in SLE, and their presence is associated with lupus nephritis.[53] In particular, the absence of anti-C1q autoantibodies is strongly associated with lack of renal involvement.[54] Because anti-C1q autoantibodies can also occur in healthy persons who do not have any renal problems, for many years it was unclear how anti-C1q autoantibodies could contribute to renal disease in persons with lupus.[33] However, mouse studies have revealed that anti-C1q autoantibodies only contribute to renal damage if sufficient immune complexes containing C1q are present in the glomeruli.[55]

Because complement seems to play such a prominent role in lupus nephritis, clinical trials have been conducted to study whether blocking complement would be beneficial.[56] However, the first small study on this topic did not reveal an effect during a relatively short follow-up period.[56]

### Rheumatoid Arthritis

A contribution of complement to the pathogenesis of RA can be concluded from the observed complement tissue deposition,[57] decreased levels of complement components in synovial fluid,[58] and the presence of complement activation fragments,[59,60] as previously reviewed.[61] However, the pronounced hypocomplementemia that is observed during flares in SLE is not observed in persons with RA. In addition, the complement deficiencies of the classical pathway that are associated with SLE may involve some arthritis but do not predispose to RA. Whereas over the years different views have existed regarding the contribution of autoantibodies, B cells, T cells, and other immune players, currently an emphasis has been placed on B cells and the autoantibodies they produce.[62] In addition to the well-known rheumatoid factor (RF), anti-citrullinated protein antibodies (ACPAs)[63] and the recently identified antibodies against carbamylated proteins (anti-CarP autoantibodies)[64] are thought to be involved in the disease process.

Interestingly, these antibodies can already be detected in serum many years before the diagnosis of RA is made.[65,66] In addition, tissue-specific autoantibodies such as anti–type II collagen may be involved in a subset of patients.[67] A contribution of these autoantibodies is inferred from the clinical associations between the presence of the antibodies and more severe joint damage.[64,67,68] However, strong experimental evidence is currently lacking to confirm a directly pathogenic role for these autoantibodies.

In vitro, ACPAs have been shown to be able to trigger complement activation.[69] Interestingly, this action was mediated not just via the expected classical pathway but also via the alternative pathway of complement activation.[69] In mouse models for arthritis, it actually seems that only the alternative pathway is essential for antibody-mediated arthritis to develop, without any essential contribution of the classical pathway.[70]

Complement activation fragments can be detected in persons with RA, but the concentrations are much higher

in synovial fluid compared with serum.[59,60,71-73] These data indicate that complement is activated not systemically but mainly locally in the affected joints. The cause of this local complement activation is not known but likely involves several sources that are not mutually exclusive. Immune complexes formed by autoantibodies binding to joint specific antigens, dead cells that accumulate during chronic inflammatory reactions in the joint, or matrix components released from damaged cartilage may all contribute to the observed complement activation.[67,69,74,75] Release of C3a and C5a, as well as sublytic insertion of the MAC, may activate immune cells, along with synoviocytes. In addition, insertion of the MAC may be involved in the generation of citrullinated antigens in the joint,[76] possibly providing antigen for ACPAs to bind to and subsequently form immune complexes.

From animal models of arthritis it may be concluded that complement plays an essential role in the development of full-blown arthritis.[61] However, at present it is not known if complement activation plays an essential role in arthritis in humans. Several clinical intervention studies aimed at blocking complement activation or inhibiting the signaling via complement receptors have been performed or are currently under way. Peptide inhibition of C5a–C5a receptor signaling has thus far been unsuccessful.[49] Humanized monoclonal antibodies targeting C5 have been proven to be well tolerated in a phase I study and additionally showed beneficial effects in a phase II study.[56] However, thus far this biologic agent has not reached clinical use, most likely for economic reasons. Other studies using a blocking antibody to the C5a receptor are currently under way. Many experimental treatments that rely on different modes of action are being tested in pre-clinical models and include active vaccination against C5,[77] locally produced blocking minibodies,[78] or targeted inhibition using constructs consisting of CR2 to bind to activated complement fragments, as well as use of factor H domains to inhibit complement.[79,80]

For other forms of arthritis, the body of evidence supporting a role for complement in the disease processes is small.[81] For example, in psoriatic arthritis, increased levels of C3 were reported with no signs of activation, likely as a result of the acute-phase response.[82] Authors of several studies reported that complement activation in osteoarthritis (OA) and spondyloarthritis either did not exist or was limited, with only low levels of complement activation in reactive arthritis.[57,82,83] More recently one paper described a role for complement activation in OA.[84] However, overall it seems that determination of the relative contribution of complement activation to the disease processes underlying these conditions would benefit from additional studies, especially in patients.

### Other Systemic Rheumatic Conditions

In many and perhaps all systemic rheumatic conditions, a role for complement can be concluded on the basis of either changed serum levels or tissue deposition of activated complement components.[81] In several conditions hypocomplementemia—that is, low C3 and/or C4—have been included in criteria and disease activity scores.[34] However, the mechanism responsible for the observed effects on complement and how this contributes to the overall disease process in these systemic rheumatic conditions remains to be established.

## CONCLUSION

In this chapter an overview of the current understanding of the role played by the complement system in health and in rheumatic conditions is provided. For many years the role of complement in rheumatic diseases was largely limited to measuring complement consumption as biomarkers of disease activity. Now, as the first drugs that target complement activation are becoming available in the clinic, a new era has begun as we begin to understand the extent to which complement activation plays an essential role in disease processes. Because of all the positive effects of complement in the body, it will need to be established whether long-term complement inhibition in rheumatic diseases will ever become standard treatment or whether it will be limited to specific clinical conditions, such as a flare of lupus nephritis. In addition, the complement biomarker field is developing rapidly, and choosing the right biomarker for a specific clinical problem is an interesting future challenge.

CHAPTER 24

# Prostaglandins, Leukotrienes, and Related Compounds

Robert B. Zurier

**KEY POINTS**

- Eicosanoid biosynthesis is catalyzed by cyclooxygenases and lipoxygenases.
- Conversion of the endoperoxide intermediate prostaglandin $H_2$ requires activity of specific terminal synthases.
- Eicosanoids and their receptors regulate inflammatory and immune responses.
- Eicosanoid synthesis is modified by administration of precursor fatty acids.

The addition of oxygen to arachidonic acid and other polyunsaturated fatty acids that are not bound to membrane phospholipids in nearly all human cell types results in the formation of several classes of bioactive products termed *eicosanoids*. Eicosanoids include prostaglandins (PGs), prostacyclin (PGI), thromboxanes (TXs), leukotrienes (LTs), and lipoxins (LXs). All of these compounds are crucial to the regulation of immunity and inflammation, among other physiologic and pathologic processes. Although eicosanoids are derived from C20 polyunsaturated fatty acids (eicosa = 20), only a small percentage of these polyenoic acids form the eicosanoids: dihomo-γ-linolenic acid (DGLA), which is 8,11,14-eicosatrienoic acid; arachidonic acid (AA), which is 5,8,11,14-eicosatetraenoic acid; and eicosapentaenoic acid (EPA), which is 5,8,11,14,17-EPA (Figure 24-1).

Two groups of fatty acids are essential to the body: the omega-6 series derived from linoleic acid (18:2 n-6) and the omega-3 series derived from α-linolenic acid (18:3 n-3). The *n* refers to the number of carbon atoms from the methyl (omega) end of the fatty acid chain to the first double bond (i.e., omega-3 and omega-6 designations). Using this notation, *18* refers to the number of carbon atoms in the fatty acid. The degree of unsaturation (the number of double carbon-carbon bonds) follows the number of carbon atoms. Fatty acids are metabolized by an alternating sequence of desaturation (removal of two hydrogen atoms) and elongation (addition of two carbon atoms). Membrane phospholipids are the main storage site for polyunsaturated fatty acids and are particularly rich in eicosanoid precursors, which are located at the sn-2 position (Figure 24-2). Because mammalian cells cannot interconvert n-3 and n-6 fatty acids, the composition of membrane phospholipids is determined by exogenous sources of fatty acids.

## BIOSYNTHESIS OF EICOSANOIDS

### Phospholipases

The presence of phospholipase A2 ($PLA_2$) in lysosomes or bound to cell membranes catalyzes the breaking of the sn-2 bond, facilitating release of AA or other polyunsaturated fatty acids (see Figure 24-2). The enzyme is crucial to regulation of eicosanoid synthesis because it is in the nonesterified state that the polyunsaturated precursors enter into the cascades, leading to eicosanoid formation. Only a scant amount of oxidation at carbon 15 of AA occurs catalytically when the fatty acid is still covalently bound as part of a phospholipid.[1]

A large number of $PLA_2$ isoforms have been characterized and grouped based on primary structure, localization, and $Ca^{2+}$ requirements.[2] Cytosolic $PLA_2$ ($cPLA_2$) group IV is the major catalyst of arachidonate release that leads to PG and LT production. The structure of $cPLA_2$ reveals a monomeric cytosolic protein with a molecular size of 85 kD. Lysophospholipids "left over" after the action of $PLA_2$ are direct precursors of platelet-activating factor (PAF), a potent mediator of inflammation, which is generated by acylation (i.e., the addition of fatty acid) in the open sn-2 position of the lysophospholipid.

Four distinct types of $PLA_2$ activities hydrolyze fatty acids esterified at the sn-2 position. Secretory $PLA_2$ ($sPLA_2$) has small disulfide cross-linked proteins that require $Ca^{2+}$ in millimolar concentrations for optimal activity. $cPLA_2$ has larger proteins requiring $Ca^{2+}$ in micromolar concentrations, which are AA selective and can deacylate diacylphospholipids completely, preventing accumulation of potentially toxic lysophospholipids. $Ca^{2+}$-independent $PLA_2$ ($iPLA_2$) exhibits specificity for plasmalogen substrates. Finally, PAF acetylhydrolase (PAF-$PLA_2$) has a series of isozymes specific for short chains.[3,4]

Under basal conditions, AA is liberated by $iPLA_2$ and then reincorporated into cell membranes (reacylated). It is unavailable for appreciable eicosanoid biosynthesis. The acylase enzymes competitively inhibit the cyclooxygenase (COX) isoenzymes. After receptor activation and cell stimulation, intra-cellular $Ca^{2+}$ levels increase and the $Ca^{2+}$-dependent $cPLA_2$ liberates arachidonate at a rate that exceeds the rate of reacylation, leading to arachidonate metabolism by COX isoenzymes and by lipoxygenases (LOs). Initial formation of prostaglandin (PG)$E_2$ seems to be due to preferential coupling among $cPLA_2$, COX-1, and cytosolic PGH-PGE isomerase. More intense inflammation leads to participation of secreted $sPLA_2$ and amplification

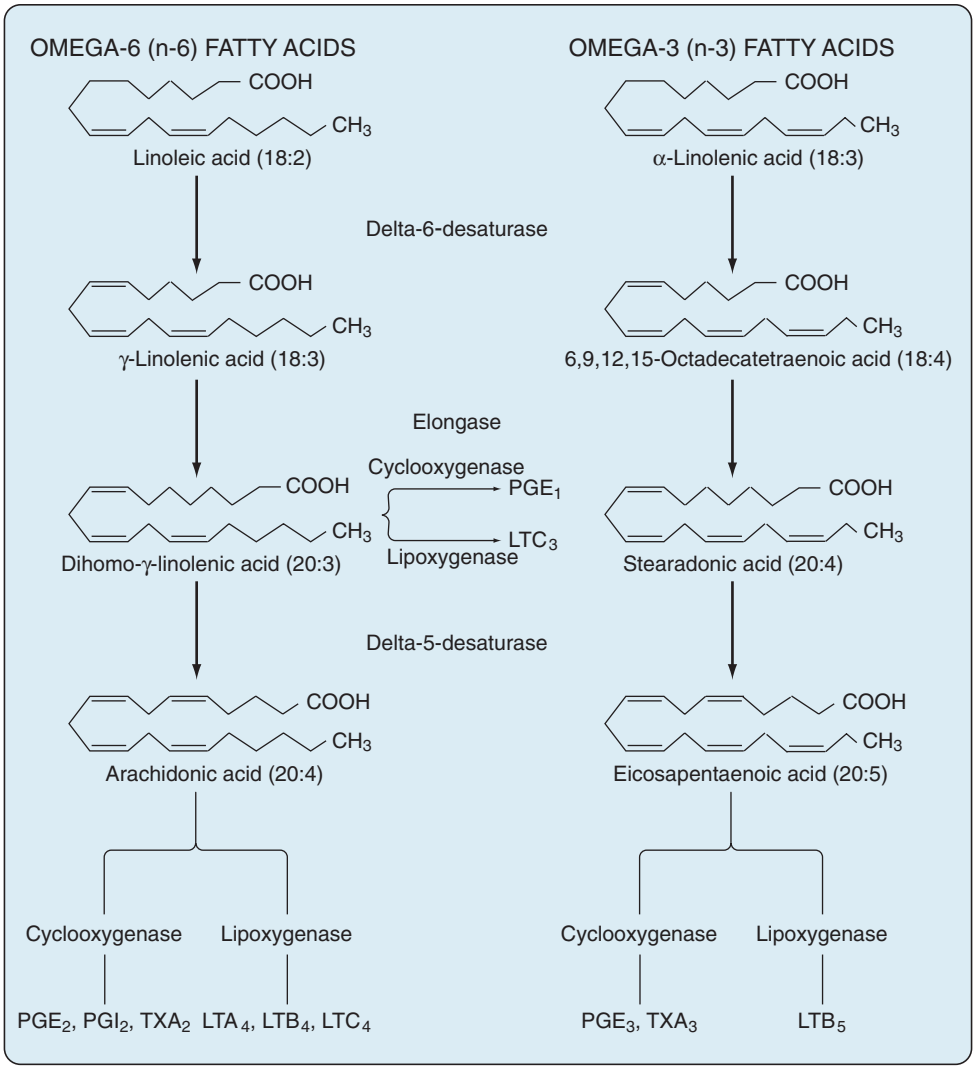

**Figure 24-1** Metabolic pathways of essential fatty acids. The pathways are ones of progressive desaturation alternating with elongation. Eicosanoid precursors include dihomo-γ-linolenic acid, arachidonic acid, and eicosapentaenoic acid. LT, Leukotriene; PG, prostaglandin; TX, thromboxane.

of $PGE_2$ biosynthesis by inducible COX-2. It is an oversimplification to regard the availability of AA as the sole rate-limiting step in cellular eicosanoid biosynthesis.

Phospholipase C (PLC) hydrolyzes the polar head group (e.g., inositol and choline) from phospholipids to yield diacylglycerol (DAG) and the polar head group. Direct protein isolation and molecular cloning studies have revealed multiple PLC isozymes in mammalian tissues. Phosphatidylinositol-PLC occurs in cytosolic (cPLC) and secreted (sPLC) forms and can be divided into three major classes (PLC-β, PLC-γ, and PLC-δ) based on substrate specificity. PLC with specificity for phosphatidylinositol and phosphorylated phosphatidylinositol is a key component of phosphatidylinositol-mediated signaling pathways. DAG is an activator of protein kinase C (PKC), and rapid production of this lipid by phosphatidylinositol-PLC hydrolysis of the phosphorylated phosphatidylinositol pool is a primary step in signaling. Further AA is made available by the sequential actions of diglyceride lipase and monoglyceride lipase.[5] PLC with activity on phosphatidylcholine has also been identified. Peripheral blood monocytes from patients with rheumatoid arthritis (RA) exhibit greater $PLA_2$ and PLC activity than do cells from healthy volunteers. $PLA_2$ concentrations did not correlate with disease activity, but the greatest increases in PLC enzyme activity were seen in cells from patients with the most severe, persistent, proliferative disease, not in cells from patients with the most active disease at the time the cells were studied.[6] In accord with the need for balance in regulation of the inflammatory response, $sPLA_2$, numbering nine members in humans, has both inflammatory and anti-inflammatory actions. Thus group V $sPLA_2$ counters the inflammatory activity of group IIA $sPLA_2$ by regulating cysteinyl LT synthesis and promoting immune complex clearance in a murine model of autoimmune erosive inflammatory arthritis. It is of interest that concentrations of IIA $sPLA_2$ are far greater than those of V $sPLA_2$ in synovial fluid from patients with RA.[7] In keeping with the fact that nothing in biology and the pathogenesis of disease is simple is the observation that treatment of patients who have RA with sPLA(2)-IIA inhibitors has only transient benefit and that sPLA(2)-IIA has activity (induction of COX-2) independent of its enzyme activity.[8]

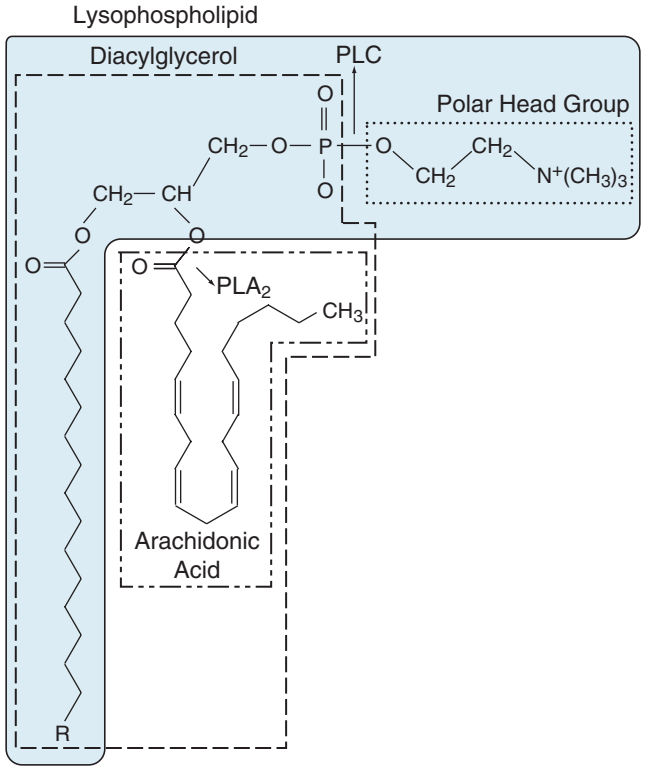

**Figure 24-2** Arachidonic acid release from phospholipid. Phosphatidylcholine, the major membrane storage site for polyunsaturated fatty acids, is depicted. $PLA_2$, Phospholipase $A_2$; PLC, phospholipase C.

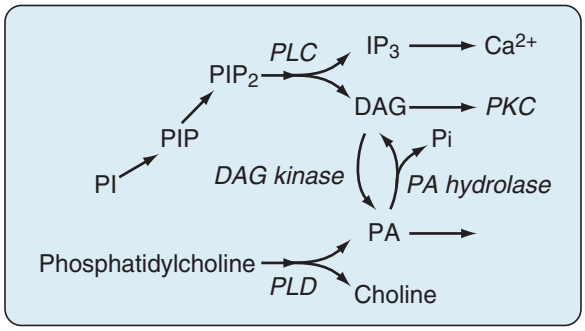

**Figure 24-3** Reactions catalyzed by phospholipases C and D, illustrating interconversion of diacylglycerol (DAG) and phosphatidic acid (PA). $IP_3$, Inositol-1,4,5-triphosphate; Pi, inorganic phosphate; PI, phosphatidylinositol; PIP, phosphatidylinositol phosphate; $PIP_2$, phosphatidylinositol-4,5-bisphosphonate; PKC, protein kinase C; PLC, phospholipase C; PLD, phospholipase D.

Hydrolysis of phospholipids by phospholipase D (PLD) produces phosphatidic acid (PA) and the respective polar head groups. The capacity of cells to interconvert PA and DAG through the action of specific cellular phosphatases and kinases (Figure 24-3) suggests that AA release from DAG and a variety of intra-cellular signaling and protein-trafficking events may be regulated by PLD activity. The targets of phosphorylation within the $PLD_2$ molecule that are key to its regulation have been mapped. PLD may be activated after or independent of PLC activation.[9]

The tetraenoic precursor (AA) is the most abundant of the three precursor fatty acids in cells of persons who eat usual Western-style diets. Metabolites of AA constitute the "2" series (dienoic) PGs (two double bonds in the molecule), and the metabolic pathway has acquired the familiar name "arachidonic acid (AA) cascade." However, diets enriched in eicosapentaenoic or γ-linolenic acid, the other eicosanoid precursors, lead to formation of different eicosanoids. Figure 24-4 illustrates the COX and 5-lipoxygenase (5-LO) pathways of the cascade.

Because phospholipases are involved in cell signaling and in acute inflammation, which sometimes escapes regulation and resolution, inhibitors of $sPLA_2$, $cPLA_2$, and PLD are being developed. It will be important to improve the selectability of these inhibitors.[10]

## Cyclooxygenase Pathway

The first step in the biosynthesis of the "prostanoids" (e.g., PGs, TXs, and PGI) is catalyzed by the bifunctional PG endoperoxide synthase 1 isozyme (also known as prostaglandin G/H synthase 1 [PGHS-1] and COX-1) and PGHS-2 (COX-2). COX is a homodimeric enzyme that integrates into only a single leaflet of the lipid bilayer of the cell membrane. The COX active site is a long hydrophobic channel. Aspirin and most other nonsteroidal anti-inflammatory drugs (NSAIDs) exclude arachidonate from the upper portion of the channel.[11] To form the characteristic five-carbon ring structure (TXs contain a six-member ring), the precursor fatty acids must have double bonds at carbons 8, 11, and 14 (numbering from the carboxyl group). When a molecule of oxygen is inserted across carbons 9 and 11, ring closure occurs enzymatically across C8 and C12, creating the unstable PG endoperoxide PGG. Subsequent peroxidation yields PGH with formation of the cyclopentane ring. PGH serves as the common precursor for PGs, PGI, and TXs that are formed under the influence of terminal synthases (see Figure 24-4). In addition to the activity of phospholipases, regulation of PG synthesis also occurs at the level of PGHS gene expression. PGHS levels are increased by interleukin (IL)-1, platelet-derived growth factor, and epidermal growth factor, which are agents that increase PG synthesis.

Cell membranes constitute the source of substrate AA and the site of action of eicosanoid-forming enzymes. PG synthesis can also form at lipid bodies, which are non–membrane-bound, lipid-rich cytoplasmic inclusions that develop in cells associated with inflammation. Lipid bodies isolated from human monocytes express PGHS activity, are reservoirs of arachidonyl phospholipids, and can function as domains of PG synthesis during an inflammatory reaction.[12]

PGHS, the well-known target of NSAIDs, exists in two isoforms. These isoforms are similar in terms of amino acid identities (about 60%), catalytic properties, and substrate specificity, but they differ in their genomic regulation.[13]

### Regulation of Cyclooxygenase-1 Expression

The gene for COX-1 *(PTGS1)* is preferentially expressed constitutively at high levels in selected cells, including endothelium, monocytes, platelets, renal collecting tubules, and seminal vesicles. Because the expression level of the enzyme does not vary greatly, it has been difficult to study

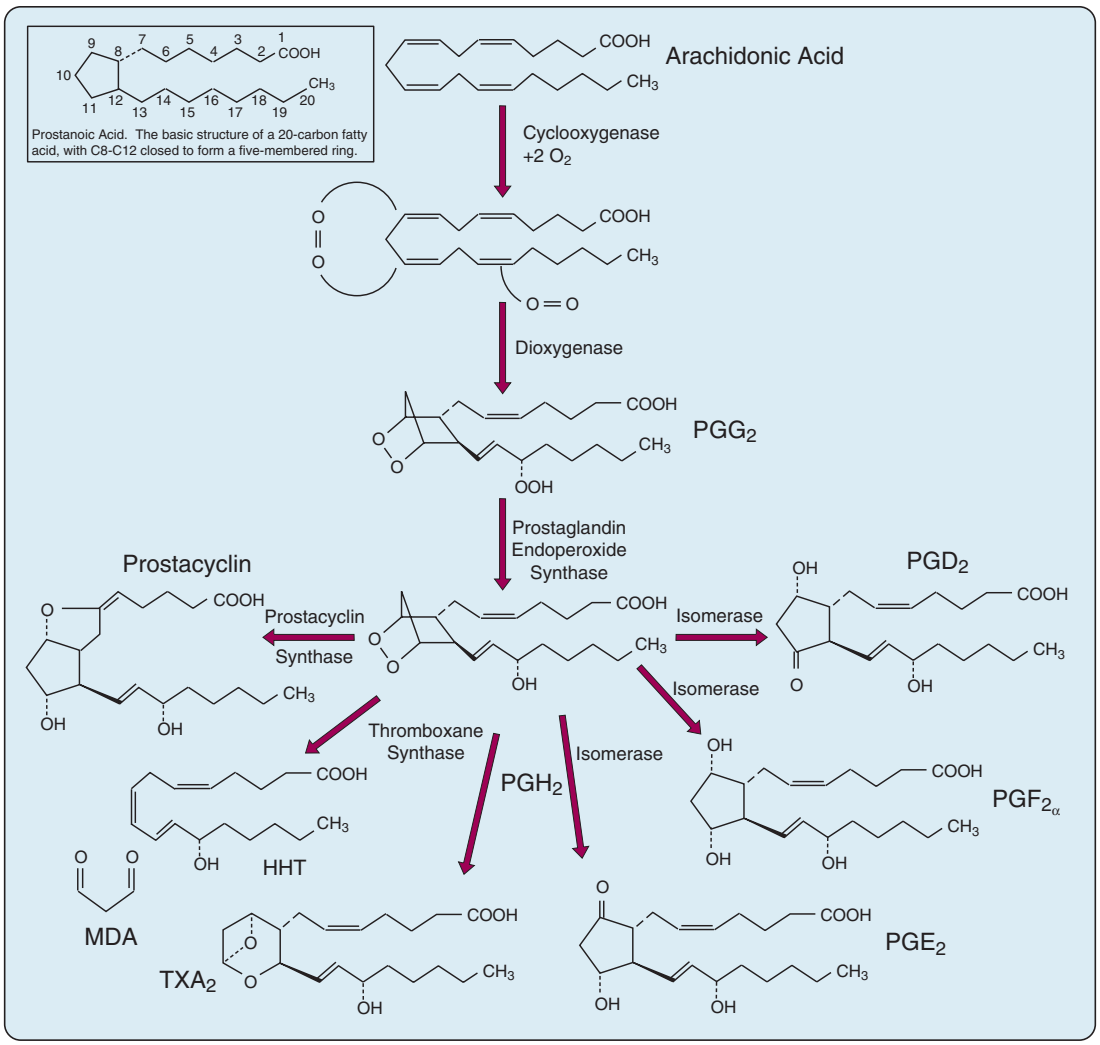

**Figure 24-4** Cyclooxygenase pathway of arachidonic acid metabolism. HHT, Hydroxyheptadeca-trienoic acid; MDA, malondialdehyde; PG, prostaglandin; TX, thromboxane.

its transcriptional regulation. The gene has a TATA-less promoter that contains multiple start sites for transcription. It is also known that Sp1/Cis regulatory elements in the promoter bond the Sp1 transcription factor to induce COX-1 gene expression. In addition, COX-1 and COX-2 splice variants may function in tissue-specific normal and pathologic processes and may represent new targets for therapy.[14] The localization of COX-1 in nearly all tissues under basal conditions suggests that its major function is to provide eicosanoids for physiologic regulation, which is seen clearly in platelets that do not have nuclei and cannot produce an inducible enzyme on activation. Rather, TXs are produced constitutively so that platelet aggregation can be completed.

### Regulation of Cyclooxygenase-2 Expression

The regulated formation of eicosanoids implies that cells have an appreciable ability to amplify the rate and amount of eicosanoid synthesis. Several processes contribute to that regulation, including silencing of $sPLA_2$ expression by COX-2 and autoinactivation ("suicide inactivation") of COX-2 and other oxygenases and synthases. In addition, the COX-2 transcript contains at least 12 copies of the AUUUA RNA motif, which makes it unstable and subject to rapid degradation. Factors that regulate COX-2 expression are specific for the physiologic processes involved. Expression of COX-2 in the macula densa in the kidney depends on luminal salt concentrations. Transcriptional activation of the COX-2 gene by mediators of inflammation such as IL-1β and tumor necrosis factor (TNF) is likely regulated by the transcription factors nuclear factor-κB (NF-κB) and CCAAT/enhancer binding protein (C/EBP). Perhaps the most crucial of the several demonstrated regulatory sequences in the 5′ flanking regions of the gene for COX-2 is the activating transcription factor/cyclic adenosine monophosphate (cAMP) response element (ATF/CRE), a site that is activated by the transcriptional activator protein-1 (AP-1) and the cAMP regulatory binding protein. Now that quantitative polymerase chain reaction analysis is routinely used to examine gene expression, it is clear that COX-2 is constitutively expressed under basal conditions at levels too low to be detected by Northern blot analysis.[15] Depending on cell and tissue specificity, several signaling

pathways (kinases, Rho, cyclic guanosine monophosphate, and Wnt) and transcription factors (NF-κB, AP-1, and NF of activated T cells [NFAT]) are involved in COX-2 expression.[16]

COX-1 and COX-2 affect a balance in several physiologic and pathologic situations. Of particular interest are their actions in the kidney and stomach. During times of low blood volume, the kidney releases angiotensin and other factors to maintain blood pressure by systemic vasoconstriction. Angiotensin also provokes PG synthesis in the kidney. COX-1, expressed in vessels, glomeruli, and collecting ducts, produces vasodilating PGs, which maintain renal plasma flow and glomerular filtration during conditions of systemic vasoconstriction. In the antrum of the stomach, COX-1 leads to production of PGs, which increase gastric blood flow and mucus secretion. Inhibition of COX-1 by NSAIDs prevents these protective mechanisms and results in renal ischemia and damage and gastric ulcers (mainly antral) in susceptible persons. These observations have led to the development of NSAIDs that selectively inhibit COX-2 and spare COX-1. AA gains access to the active site of the COX via a hydrophobic channel, and access is blocked by insertion of an acetyl residue on serine 530 in COX-1 and serine 516 in COX-2. The irreversibility of the interaction and the unique expression of COX-1 in the anucleate platelet is the reason for the clinical efficacy of low-dose aspirin. Nonacetylated NSAIDs compete with arachidonate for the active site and can interfere with the sustained effects of aspirin. Although the structures of COX isozymes are similar, COX-2 is characterized by a side-pocket extension to the hydrophobic channel, which is where the selective COX-2 inhibitors localize.[13]

The major adverse effects of NSAIDs, gastroduodenal injury, and impaired renal function, as well as the induction of myocardial infarction and stroke, are caused by inhibition of COX-1, whereas the analgesic and anti-inflammatory activities of NSAIDs rest in part on their ability to inhibit COX-2. However, COX-2 also seems to have a regulating role in renal, brain, gastrointestinal, ovarian, and bone function. COX-2 is also expressed in endothelial cells, and its inhibition suppresses prostacyclin synthesis by endothelial cells.[17] COX-2 acts in the initiation and resolution of inflammation. Its expression increases transiently early in the course of carrageenan-induced pleurisy in rats. Later in the response, COX-2 is expressed at even higher levels, leading to synthesis of $PGD_2$ and its dehydration product 15-deoxy-δ12,14-$PGJ_2$ (15δ$PGJ_2$). Early expression of COX-2 is associated with production of inflammatory PGs, whereas the later peak results in production of PGs that suppress inflammation.[18] That inflammation occurs in COX-2 knockout mice[19] reminds us, as Lewis Thomas stated,[20] "inflammation will take place at any cost." Nonetheless, the search for more selective and localized COX-2 inhibition continues. One strategy is achieved by using the mechanism of RNA interference (RNAi). Nonpathogenic *Escherichia coli* are engineered to invade tumor cells (and perhaps could be designed to invade synovial cells) and to generate anti–COX-2 small interfering (si)RNA molecules (siCOX-2), thereby silencing overexpressed COX-2. The involvement of micro (mi)RNAs in COX-2 post-transcriptional regulation suggests a possible endogenous silencing mechanism to reduce COX-2 expression.[21]

### Cyclooxygenase-3

Acetaminophen, similar to NSAIDs, suppresses pain and fever. However, acetaminophen is not an anti-inflammatory agent, and despite its extensive use, its mechanism of action has not been apparent. The finding that acetaminophen inhibits COX activity more in canine brain homogenates than in spleen homogenates gave rise to the concept that variants of the COX enzyme exist that are differentially sensitive to acetaminophen. COX-3 is a splice variant of COX-1 that retains the intron-1 gene sequence at the messenger (m)RNA level, which encodes a 30 amino acid sequence inserted into the N-terminal hydrophobic signal peptide of the enzyme protein. COX-3 protein and mRNA transcripts have been identified in human tissues, as well as in rats. They have been found most abundantly in the cerebral cortex and heart, although the mechanism for conversion of COX-3 mRNA to active enzyme is not clear.[11,22] These findings led to a search for other COX variants. A COX-2 variant induced by 0.5 mM diclofenac via stimulation of the nuclear receptor peroxisome proliferator-activated receptor γ (PPARγ) (the receptor for the pro-resolving 15-deoxy-δ12,14 $PGJ_2$) has been discovered. Whereas induction of COX-2 by lipopolysaccharide (LPS) results in release of the inflammatory cytokines IL-6 and TNF, diclofenac-induced COX-2 leads to release of the anti-inflammatory cytokines transforming growth factor (TGF)-β and IL-10.

### Prostaglandin Synthases

Conversion of the endoperoxide intermediate $PGH_2$ to PGs requires the activity of specific terminal synthases. Hematopoietic PGD synthase (H-PGDS) catalyzes the isomerization of $PGH_2$ to $PGD_2$ in immune and inflammatory cells. Cytosolic PGE synthase (cPGES) is responsible for constitutive expression of $PGE_2$, and microsomal PGE synthase 1 (mPGES-1) induces PGE in response to inflammatory stimuli. At least 10 enzymes convert PG precursors into biologically active PGs, and reactive oxygen species generated during an inflammatory response lead to expression of mPGES-1.[23,24] Suppression of PG synthase activity might be considered as an alternative strategy that would fall between global blockade by inhibition of COX and blockade of a single eicosanoid receptor. Increased fibrosis may now be added to the well-known adverse effects of NSAIDs, including COX-2 selective agents.[25] Thus efforts have been directed at development of drugs that inhibit mPGES-1, rather than COX-2, thereby suppressing $PGE_2$ production while sparing production of prostacyclin.[26] Because $PGE_2$ is also important to the induction of matrix metalloproteinases (MMP)-3 and MMP-13, suppression of mPGES-1 might counteract articular cartilage degradation in patients with inflammatory arthritis.[27]

## PRODUCTS OF THE CYCLOOXYGENASE PATHWAY

### Prostaglandins

The basic structure of all PGs is a "prostanoic acid" skeleton, that is, a 20-carbon fatty acid with a five-membered

ring at C8 through C12 (see Figure 24-4, *inset*). The term *prostaglandins* is employed widely but should be used only to describe the oxygenation products that contain the five-membered carbon ring. A family of acidic lipids found first in human seminal fluid, PGs were misnamed because it was thought they were produced in the prostate gland rather than in the seminal vesicles.[28-30] The alphabetic PG nomenclature (e.g., PGE, PGF, and PGD) is related to the chemical architecture of the cyclopentane ring. PGE and PGF differ only in the presence of a ketone or hydroxyl function at C9 (see Figure 24-4). These compounds are made by different enzymes (e.g., $PGE_2$ and $PGD_2$ are made by isomerases, and $PGF_{2\alpha}$ is made by a reductase). In the nomenclature, a subscript numeral after the letters indicates the degree of unsaturation in the alkyl and carboxylic acid side chains. The numeral *1* indicates the presence of a double bond at C13-C14 ($PGE_1$), *2* marks the presence of an additional double bond at C5-C6 ($PGE_2$), and *3* denotes a third double bond at C17-C18 ($PGE_3$).

PGs are produced on demand and seem to exert their effects on the cell of origin or nearby structures. They are not stored in cells and are degraded rapidly in vivo by 15-hydroxyprostaglandin dehydrogenase (PGDH) during one passage through the lungs. Abundant experimental evidence supports the view that PGs participate in development of the inflammatory response. $PGE_2$ is a central component of the inflammasome-dependent induction of the eicosanoids that leads to loss of intravascular fluid.[31] However, PGs are probably better at potentiating the effects of other mediators of inflammation than they are at inducing inflammation directly. PGE compounds and intermediate hydroperoxides of AA increase pain sensitivity to bradykinin and histamine. The effects of PGE are cumulative, depending on concentration and time. Even small amounts of PGs, if allowed to persist at the site of injury, may in time cause pain.

$PGE_2$ stimulates bone resorption,[32] and its 13,14-dihydro derivative is nearly as potent, which is of interest because derivatives of the biologically active PGs are usually assumed to be of no functional significance. Addition of serum to the culture medium stimulates bone resorption, a process that is complement dependent and PG mediated. The mechanism may help explain bone erosion in joints of patients with RA, in which complement is activated and $PGE_2$ concentrations are high. The observation that $PGE_1$ can stimulate bone formation[33] suggests that PGs physiologically participate in coordination of bone formation and resorption. For example, primary idiopathic hypertrophic osteoarthropathy, a familial disorder, is associated with mutations in PGDH and subsequent impairment of PG degradation. These patients have chronically elevated levels of PGE and exhibit digital clubbing and evidence of both increased bone formation and resorption in their phalanges.[34] Many effects of IL-1 and TNF on cells are associated with stimulation of PG production and inflammation. Cartilage explants from patients with osteoarthritis express COX-2 (but not COX-1) and release 50 times more $PGE_2$ in culture than does cartilage from healthy subjects and 18 times more $PGE_2$ than does normal cartilage stimulated with cytokines plus LPS. Explants from patients with osteoarthritis release IL-1β, whereas normal cartilage does not express mRNA for pro–IL-1β or release IL-1β spontaneously. It seems that in osteoarthritis—and probably in RA—upregulation of cartilage IL-1β and subsequent production of $PGE_2$ leads to cartilage degradation.[35,36]

Mast cells, often overlooked as important in inflammatory responses, are seen in large numbers in synovium from patients early in the course of RA.[37] $PGD_2$, the major PG formed by mast cells, is also produced by eosinophils and type 2 (T helper [Th]2) lymphocytes. $PGD_2$ induces chemotaxis of Th2 cells via activation of the chemoattractant receptor-homologous molecule (CRTH2) expressed on Th2 cells, and CRTH2 antagonists block that action and reduce allergen-induced inflammation. $PGJ_2$, formed from the dehydration of $PGD_2$, functions as a brake on the inflammatory response. It reduces macrophage activation, reduces nitric oxide production from stimulated cells, and induces apoptosis in tumor cell lines. $PGJ_2$ is metabolized to 15-deoxy-δ12,14 $PGJ_2$ and δ12 $PGJ_2$, which are also biologically active.[38] The biologic activity of PGA, formed from loss of water from the cyclopentane ring, is not completely clear. However, in vitro, $PGA_2$ induces apoptosis in HL-60 cells and acts through a nuclear receptor to increase insulin sensitivity.[39]

## Prostacyclin

PGI, discovered in 1976,[40] has been purified, and the complementary (c)DNA for PGI synthase has been cloned. In addition to a cyclopentane ring, a second ring is formed by an oxygen bridge between carbons 6 and 9. PGI is generated from $PGH_2$ by a distinct prostacyclin synthase, a 56 kDa member of the cytochrome P-450 superfamily of enzymes found predominantly in endothelial and vascular smooth muscle cells.[15] Production of PGI can be stimulated by thrombin or generated by transfer of $PGH_2$ from platelets (the endoperoxide steal), or it can be stimulated by contact with activated leukocytes or by stretching of the arterial wall. PGI is a powerful vasodilator that inhibits platelet aggregation through activation of adenylate cyclase, which leads to an increase in intra-cellular cAMP. It is metabolized rapidly (the half-life in plasma is less than one circulation time) to the more stable, less biologically active 6-keto-$PGF_{1\alpha}$. The enzymatic products of its conversion—2,3-dinor-6-keto $PGF_{1\alpha}$ and 6,15-di-keto-2,3-dinor $PGF_{1\alpha}$—are also chemically stable and have little biologic activity. They are the major metabolites of prostacyclin excreted in urine, in which they can be assayed as indicators of PGI generation.

PGI generated in the vessel wall has anti-platelet and vasodilator actions, whereas $TXA_2$ generated by platelets from the same precursors induces platelet aggregation and vasoconstriction. These two eicosanoids represent biologically opposite poles of a mechanism for regulating the interaction between platelets and the vessel wall and of formation of hemostatic plugs and intra-arterial thrombi. Given the central role of platelets in inflammatory reactions, an appropriate PGI-TX balance is important to regulation of inflammation. The balance may be altered in patients with anti-phospholipid antibody syndrome, in patients treated with cyclosporine, and in patients treated with NSAIDs, especially patients treated with selective COX-2 inhibitors. Although COX-2 inhibitors reduce recurrence of colorectal

adenomas, they increase the risk for cardiovascular events, such as myocardial infarction and stroke.[41]

Intravascular infusion of PGI also reduces some of the clinical changes associated with pulmonary embolism. The instability of PGI makes it cumbersome to administer therapeutically. Nonetheless, it has been used with limited success to treat peripheral vascular disease, including Raynaud's phenomenon. New therapeutics for treatment of pulmonary hypertension, including patients with sarcoidosis and systemic sclerosis, are PGI analogues and PGI receptor antagonists.[42,43] Inhaled PGI analogues may help overcome some of the adverse effects due to intravenous administration of these drugs.[44]

## Thromboxanes

The endoperoxide $PGH_2$ can be converted into TXs after the action of the enzyme TX synthase, a microsomal 60 kDa member of the cytochrome P-450 family, which is quite active in the platelet. The gene that encodes the enzyme has been cloned. TXs contain a six-member oxane ring instead of the cyclopentane ring of the PGs. TX synthase converts $PGH_2$ into equal amounts of $TXA_2$ and 12L-hydroxy-5,8,10-heptadecatrienoic acid. $TXA_2$ stimulates platelet activation, contributes to intravascular aggregation of platelets, and contracts arteriolar and bronchiolar smooth muscles. It is hydrolyzed rapidly (the half-life is 30 seconds) to the inactive, stable, measurable product, $TXB_2$; its actions are limited to the microenvironment of its release.

The extraordinary rapidity with which platelets adhere to damaged tissue, aggregate, and release potent biologically active materials suggests that the platelet is well suited to be a cellular trigger for the inflammatory process. Efforts directed at suppression of TX synthesis and platelet aggregation may result in limitation of inflammatory responses, especially in coronary arteries. Inhibition of platelet aggregation may be important to the anti-inflammatory effects of aspirin and other NSAIDs. Long-term administration of low doses of aspirin (40 mg/day—the lowest dose predicted to cause total inhibition of TX formation in serum, according to mathematic modeling) has inhibitory effects on platelet function ex vivo that are indistinguishable from the effects caused by giving 325 mg/day of aspirin.[45] Aspirin acetylation of COX in platelets occurs in the portal vein, where the aspirin concentration is high before it is metabolized in the liver, which explains why the 81-mg dose of aspirin is so effective in prevention of heart attacks and strokes. Platelets lose their ability to aggregate until new platelets are formed in about a week.[11] Nonetheless, the response to aspirin can vary among individuals. Biomarker testing for TX production and assessment of aspirin efficacy—which is not done as routinely as necessary—can reduce the risks associated with aspirin therapy.[46] High platelet turnover in some patients with chronic inflammation may diminish the efficacy of aspirin, a phenomenon termed *aspirin resistance*.[47]

Selective inhibition of TX synthase represents an approach that may be used to suppress $TXA_2$ synthesis without depressing prostacyclin formation. The endoperoxide steal seems to function in vivo after administration of a TX synthase inhibitor. Antagonists of the receptors shared by endoperoxide and $TXA_2$ have been developed, and these agents inhibit platelet aggregation in patients who are recalcitrant to TX synthase inhibition. Novel agents targeting TX receptors and TX synthase have improved treatment of vasculitis and cardiovascular and renal diseases.[48] More specific inhibition of TX action may become possible now that TX receptors have been cloned and characterized.[49]

## Lipoxygenase Pathways

In contrast to the COX pathway, in which stable products have three atoms of oxygen covalently attached to AA from 2 moles of molecular oxygen, LOs insert a single oxygen atom into the molecular structure of AA. Separate LOs exist in certain cells and have strict structural requirements for their substrates. Three major mammalian LOs insert their oxygen atoms into the 5, 12, or 15 position of AA, with formation of a new double bond and hydroperoxy group. The hydroperoxy fatty acids (hydroxyperoxyeicosatetraenoic acid [HPETE]) can be reduced by peroxidases in the cell to yield the corresponding hydroxy fatty acids (hydroxyeicosatetraenoic acid [HETE]). The exclusive LO product of the human platelet is 12-HPETE, which, upon reduction of the hydroperoxy group, yields 12-HETE. In contrast, the human neutrophil makes predominantly 5-HPETE, but when high concentrations of AA are added, cells exhibit 15-LO. LOs that act on AA are found in the cytosol fraction of cells.

The human 5-LO gene has been isolated and characterized[50,51] and produces a 78 kDa enzyme. In myeloid cells the 5-LO pathway leads to formation of the biologically active LTs (Figure 24-5) that were originally found in leukocytes and that contain three conjugated double bonds (trienes). Cell activation leads to translocation of 5-LO from cytosol to the nuclear membrane, where it encounters the 18 kDa, 5-LO–activating protein (FLAP). AA is also translocated to FLAP for presentation to 5-LO. In addition, upon cell stimulation, $cPLA_2$ is activated and also associates with the nuclear membrane, close to FLAP. Thus FLAP inhibition represents an approach to suppression of inflammation.[52] The ability of macrophages and dendritic cells to respond appropriately during innate immune responses is likely regulated by 5-LO and 12-LO.[53] The unstable HPETE is the initial metabolite of each LO pathway. HPETE is reduced to the more stable HETE or is converted by 5-LO to $LTA_4$. $LTA_4$ can be converted to $LTB_4$ (in neutrophils and macrophages) or conjugated with reduced glutathione to form $LTC_4$ (in eosinophils, mast cells, endothelial cells, and macrophages). In contrast to LO, which is mainly distributed in myeloid cells, $LTA_4$ hydrolase (5,12-dihydroxyeicosatetraenoic acid), a zinc-requiring enzyme that converts $LTA_4$ to $LTB_4$, is widely distributed. From the cDNA sequence, it was suggested that mRNA for $LTA_4$ has a short half-life, which accounts for the properties of extremely rapid production and shutdown of $LTB_4$ and other eicosanoid biosynthesis.

$LTA_4$ can be exported from the cell of origin and converted in other cells by $LTA_4$ hydrolase to $LTB_4$. This variation on the endoperoxide steal—perhaps better called *transcellular metabolism*—also applies to conversion of $LTA_4$ to $LTC_4$ by $LTC_4$ synthase, a glutathione-*S*-transferase.[54] Although human endothelial cells do not produce terminal

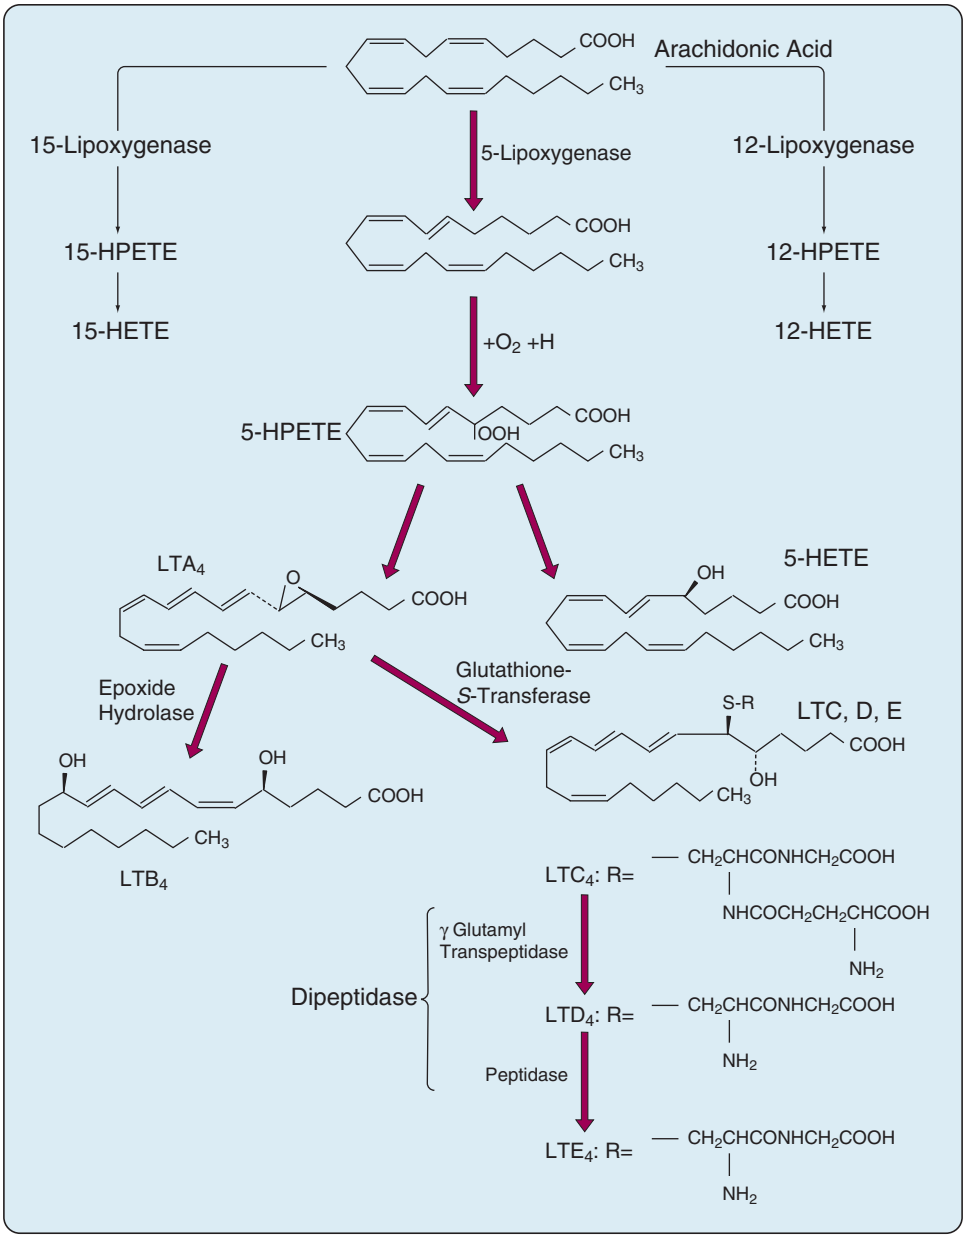

**Figure 24-5** 5-Lipoxygenase pathway of arachidonic acid metabolism. HETE, Hydroxyeicosatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid; LT, leukotriene.

products of the 5-LO system, they do generate $LTC_4$ from $LTA_4$ provided by neutrophils. $LTC_4$ and its products, $LTD_4$ and $LTE_4$, constitute the biologic mixture previously known as slow-reacting substance of anaphylaxis. $LTD_4$ and $LTE_4$ arise from $LTC_4$ after sequential removal of γ-glutamic acid and glycine from $LTC_4$. The enzyme γ-glutamyl transpeptidase is present in many cells as part of a complex enzymatic system involved in glutathione biosynthesis and amino acid transport. In many systems the major sulfidopeptide LT has been reported to be $LTD_4$, rather than the precursor $LTC_4$. Removal of glycine from $LTD_4$ results in $LTE_4$, with concomitant loss of a significant amount of biologic activity. The principal route of inactivation of $LTB_4$ is by omega oxidation.

## Products of the Lipoxygenase Pathways

The biologic effects of compounds produced in the LO pathway indicate their importance in inflammatory diseases.[55] They are the major mediators of inflammation formed by the oxygenation of AA and are implicated as key mediators in several diseases, including inflammatory bowel disease, systemic sclerosis, psoriasis, and RA.

5-HETE and 5-HPETE stimulate the generation of superoxide in human neutrophils. These compounds also augment intra-cellular calcium levels, facilitating PKC-dependent activation of a superoxide-generating system of neutrophils. $LTB_4$ increases adherence of leukocytes to endothelial cells, a response that is augmented by exposure of the endothelial cells to TNF. $LTB_4$ does not seem to have

a direct vascular contractile action because it is inactive in the hamster cheek pouch preparation and several other microvasculature systems. In rabbit skin, administration of $LTB_4$ with a vasodilator PG induces plasma exudation, which suggests that $LTB_4$ may assist enhanced vascular permeability. Increased venule permeability does occur in response to $LTC_4$, $LTD_4$, and $LTE_4$. $LTB_4$ is a potent chemotactic factor for neutrophils and is weakly chemotactic for eosinophils. $LTB_4$ and, to a lesser extent, 5-HETE enhance migration of T lymphocytes in vitro. Synovial cells produce 5-HETE but do not produce significant amounts of $LTB_4$. However, macrophages that invade the synovium in patients with RA generate substantial quantities of 5-lipoxygenation and 15-lipoxygenation products, including $LTB_4$. In addition to local signs of inflammation induced by products of the LO pathway, these compounds may contribute to the pain, tenderness, and aching common in patients with RA. $LTB_4$ also seems to serve an immunoregulatory function. It stimulates differentiation of competent $CD8^+$ T lymphocytes from precursors lacking the CD8 marker. $LTB_4$ also stimulates interferon (IFN)-γ and IL-2 production by T cells and biosynthesis of IL-1 by monocytes.[56]

Synovial cell proliferation and endothelial cell proliferation are central to propagation of the rheumatoid joint lesion. $LTB_4$ and the cysteinyl LTs act as growth or differentiation factors for several cell types in vitro. These compounds also increase proliferation of fibroblasts when PG synthesis is inhibited.[57] These findings emphasize the importance of interactions between the COX and LO pathways and suggest limitations to NSAID therapy for patients with RA.

Strategies for inhibiting production or antagonizing the actions of LTs include development of selective LT receptor antagonists and inhibition of the production of LT by blocking the action of 5-LO. Inhibition of enzymes distal in the LT cascade, such as $LTA_4$ hydrolase,[58] is also a promising strategy for development of anti-inflammatory drugs. A compound that inhibits binding of 5-LO to FLAP exhibits anti-inflammatory effects in animal models. Although LO inhibitors have not been very useful for treatment of patients with inflammatory diseases, development of new compounds, based on a better understanding of the molecular aspects of inhibitory activities, seems more promising.[59] In addition, the existing agents may be aiming at the wrong target. Fibroblasts such as synovial cells do not make much $LTB_4$, but they do make 12-HETE, a growth factor, through a cytochrome P-450 pathway.[60] Cytochrome P-450 inhibitors may be more to the therapeutic point.[61]

LO activities do not lead solely to production of mediators of inflammation. DGLA is converted by 15-LO into 15-HETE, which is incorporated into DAG and exerts anti-inflammatory effects partly by interfering with PKC-β activity. An LO product of linoleic acid, 13-hydroxyoctadecadienoic acid, also suppresses inflammation and cell proliferation by a similar mechanism.[62] EPA is converted by LO into 15-hydroxyeicosapentaenoic acid, which also exhibits anti-inflammatory properties.[63]

## Lipoxins

Another large family of AA metabolites arises from the sequential action of 5-LOs and 15-LOs. Addition of 15-HPETE and 15-HETE to human leukocytes results in formation of a pair of oxygenated products containing a unique conjugated tetraene. One compound ($LXA_4$) was identified as 5,6,15L-trihydroxy-7,9,11,13-eicosatetraenoic acid, and the other proved to be its positional isomer ($LXB_4$), 5D-14,15-trihydroxy-6,8,10,12-eicosatetraenoic acid (Figure 24-6). Because both of these compounds can arise through an interaction between LO pathways, the trivial name *lipoxins* (i.e., lipoxygenase interaction products) was introduced. Platelet 12-LO can transform neutrophil $LTA_4$ to LXs. The complete stereochemistry and multiple routes of biosynthesis for the biologically active $LXA_4$ and $LXB_4$ have been determined.[64]

The fact that macrophages of rainbow trout generate LXs rather than LTs or PGs as their major products of AA metabolism indicates that LXs have a long evolutionary

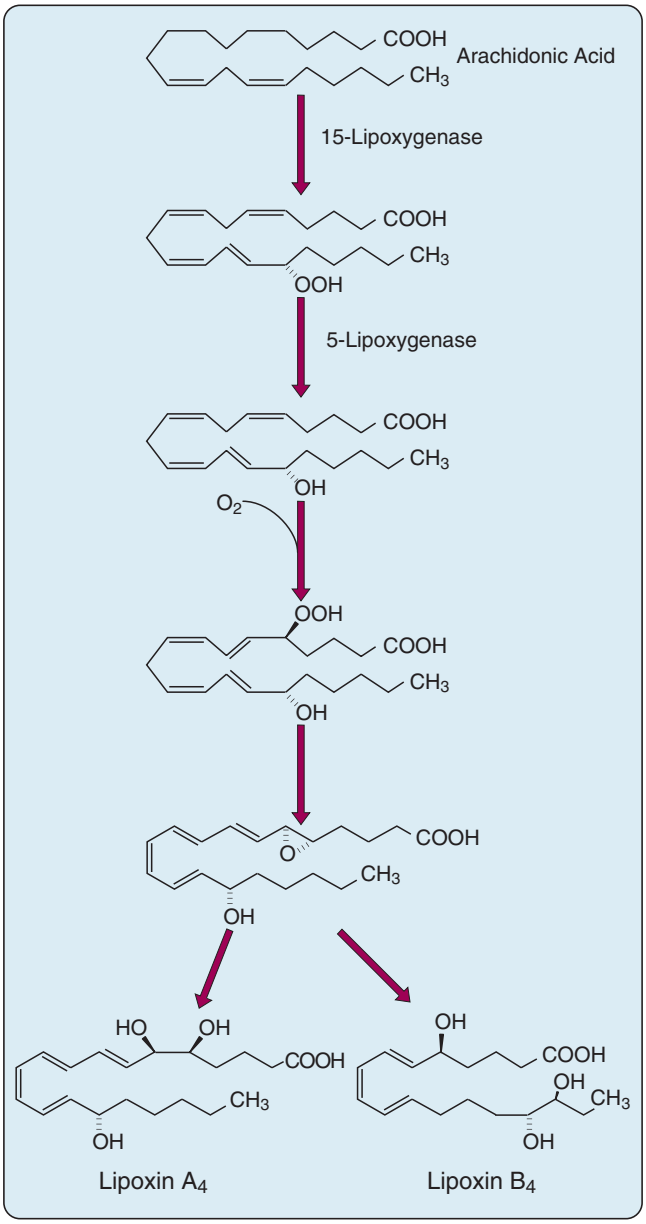

**Figure 24-6** Lipoxin biosynthesis. The lipoxins result from the sequential action of 15-lipoxygenase and 5-lipoxygenase on arachidonic acid.

history. LTs and LXs can be generated in parallel in fish. In humans, the process has diverged to a two-cell system. Biosynthesis of eicosanoids by transcellular and cell-cell interactions is recognized as an important way to generate and amplify lipid-derived mediators. LXs can be generated within the vascular lumen during platelet-leukocyte interactions and at mucosal surfaces via leukocyte–epithelial cell interactions. In humans, LXs are formed in vivo during multicellular responses such as inflammation, atherosclerosis, and in asthma. These tetraene-containing products serve as stop signals in that they prevent leukocyte-mediated tissue injury. Acute inflammation is a primitive protective response,[65] and chronic inflammation involves failure of mechanisms designed to stop the acute response. A major problem in joints of patients with RA, and of patients with other conditions associated with chronic inflammation and tissue injury, is that inflammation often does not resolve. LXs and aspirin-induced 15-epilipoxins are endogenous components of events governing resolution of inflammation. Aspirin acetylation of COX-2 in endothelial cells suppresses PG synthesis but leads to generation of 15R-HETE from AA, which is transformed to 15-epilipoxin by leukocytes in a transcellular biosynthetic route involving vascular endothelial cells or epithelial cells. These 15-epilipoxins exhibit anti-inflammatory and anti-proliferative actions in vitro and in vivo. Stable analogues of $LXA_4$ and of aspirin-triggered LX (ATL) also suppress inflammation in animal models. In addition, acting as antagonists at the receptor CysLT1, ATL analogues counteract the inflammatory actions of cysteinyl LTs.[66] These observations may lead to the development of new anti-inflammatory drugs. For example, induction by IFN of particular genes is important to the pathogenesis of systemic lupus erythematosus (SLE). A stable synthetic analogue of $LXA_4$ suppresses several IFN-induced genes and reduces kidney damage in a murine model of immune-mediated nephritis.[67]

LXs block human polymorphonuclear leukocyte chemotaxis but stimulate monocyte chemotaxis and adherence. Monocytes do not release mediators of inflammation in response to LXs, however, and LXs are converted rapidly by monocytes to inactive compounds. This selective effect on chemotaxis suggests that LXs play a role in wound healing. $LXA_4$ antagonizes $LTD_4$-induced vasoconstriction in vivo and blocks binding of $LTD_4$ to its receptors on mesangial cells. $LXA_4$ suppresses $LTB_4$-induced plasma leakage and leukocyte migration and blocks $LTB_4$-induced neutrophil inositol triphosphate generation and calcium mobilization, but not superoxide anion generation. Conversely, $LXA_4$ activates PKC and is more potent in this regard than DAG and AA. $LXA_4$ seems to be specific for the γ subspecies of PKC. These results indicate that LXs regulate the actions of vasoconstrictor LTs and suggest that $LXA_4$ may be an important modulator of intra-cellular signal transduction.

It was long thought that resolution of inflammation was a passive process. Contrary to this belief, the inflammatory response does not dissipate but is mediated actively by products of COX and LO and acetylation of these enzymes.[68] Discovery that omega-6 and omega-3 polyunsaturated fatty acids are also substrates for enzymatic oxygenation reactions that produce lipid mediators with potent anti-inflammatory and proresolution actions has advanced our understanding of the inflammatory response. In addition to LXs, entire spectra of specialized pro-resolving mediators (SPM) have been uncovered. These SPMs include resolvins, protectins, and maresins.[69] Like LXs, resolvins are formed via specific transcellular biosynthetic pathways from both n-6 and n-3 fatty acids. EPA-derived (E series) cellular interaction products formed in resolving exudates have been termed *resolvins* (RvE1, RvE2, and RvE3). The omega-3 docosahexaenoic acid (DHA) can be catalyzed via the 15-LO pathway to dihydroxy products (D series resolvins D1-D5) that also stimulate resolution of inflammation and enhance innate host defense mechanisms. LXs and resolvins act as endogenous receptor agonists at low concentrations (pM to nM) and at specific G protein–coupled membrane spanning receptors to actively downregulate inflammatory events and to stimulate resolution of an inflammatory exudate. A single cell type can also form oxygenated lipid mediators with counter-regulatory actions. DHA can also be catalyzed via the 15-LO pathway to a dihydroxy product termed *protectin D1* (PD1), which can protect against tissue damage and activate resolution of inflammation. In a second single oxygenation route, a lipid mediator termed *maresin* (macrophage mediators in resolving inflammation) is formed via the action of human 12-LO. The maresin biosynthetic pathway is activated in macrophages during phagocytosis. Maresin 1 (MaR1) reduces neutrophil migration and increases macrophage phagocytosis of apoptotic cells, thereby exhibiting the hallmarks of SPM. It now seems clear that failure of resolution programs contributes to progression of diseases characterized by chronic inflammation.[70]

## Isoeicosanoids

Isoeicosanoids, which are isomers of enzymatically derived eicosanoids, are derived from the free radical–mediated peroxidation auto-oxidation of both omega-6 and omega-3 fatty acids.[71] Isoeicosanoids include members of the F, D, and E isoprostanes, isothromboxanes, and isoleukotrienes. Analysis of the isoprostanes indicates that they reflect lipid peroxidation in vivo and are therefore used as markers of oxidative stress. One F-type isoprostane, isoprostane $F_{2\alpha}$ III (formerly 8-isoprostaglandin $F_{2\alpha}$), has been studied in detail because of its biologic activity in vitro. Isoprostane $F_{2\alpha}$ III (Figure 24-7) is a potent vasoconstrictor and may function as a mitogen, with actions that are blocked by TX receptor antagonists. Although isoprostanes may act as ligands at TX or PG receptors (e.g., 8,12-isoprostane $F_{2\alpha}$ III activates the $PGF_{2\alpha}$ receptor), they also activate specific isoprostane receptors.

### Isoprostanes

What all isoprostanes have in common, and what distinguishes them from the PGs, is the fact that the top (α) and the bottom (ω) side chains are always syn—that is, crowded together on the same face of the cyclopentane ring. The minimal requirement for generation of an isoprostane is a polyunsaturated fatty acid with three contiguous methylene-interrupted double bonds, a requirement met by dozens of naturally occurring polyunsaturated fatty acids. Brain tissue contains particularly high levels of fatty acids formed from DHA (C22:6 n-3). By the same peroxidation process undergone by AA, DHA in nerve cell membranes is converted

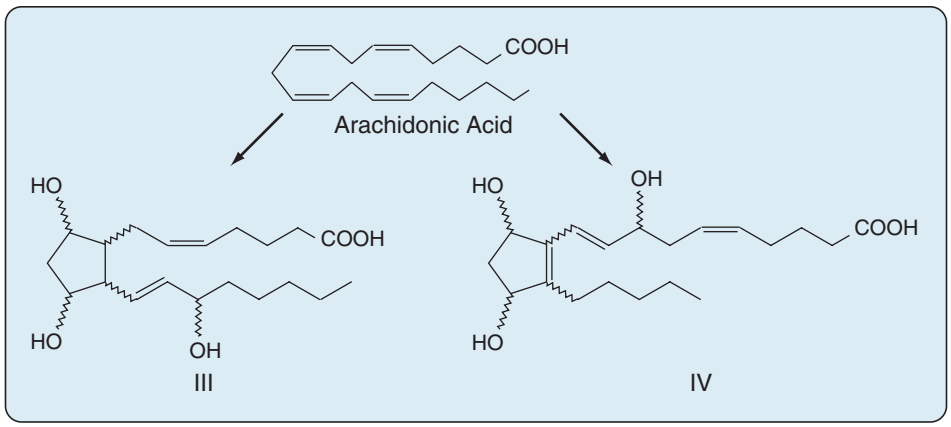

**Figure 24-7** Isoprostane $F_{2\alpha}$ structures. *Jagged lines* indicate that stereochemistry is uncertain.

to several neuroprostanes. Of these, F4-neuroprostane is a biomarker for several neurodegenerative diseases. A similar mechanism in plants yields phytoprostanes from α-linolenic acid. In contrast to conventional, enzymatically derived PGs that are formed intra-cellularly and released immediately, isoprostanes are formed in the cell membrane, cleaved by phospholipases, circulate in plasma, and are excreted in urine. As stable end products of lipid peroxidation, endogenously formed isoprostanes are useful markers of oxidative stress and independent risk markers for coronary artery disease. They are increased in several diseases, including acute respiratory distress syndrome, in which polymorphonuclear leukocytes generate reactive oxygen species that damage pulmonary epithelium. The immune cells in inflamed tissues are exposed to reactive oxygen intermediates produced by neutrophils and other phagocytic cells. Oxidants are also generated as mediators in intra-cellular signaling pathways by cytokines such as IL-1β and TNF. Isoprostanes are important to and are biomarkers for inflammatory conditions such as vasculitis and RA, and they are assayed in biologic fluids and tissues. Because isoprostanes are released pre-formed, their production is not blocked by NSAIDs, which suppress metabolism of free AA. It is possible that inflammation that is unresponsive to NSAIDs may yield to inhibition of isoprostanes. In keeping with the notion of eicosanoids as regulators, however, some isoprostanes suppress release of mediators of inflammation from macrophages, and a phytoprostane (E1-phytoprostane) signals through PPARγ and NF-κB to suppress IL-12 production by activated dendritic cells and to reduce cytokine production by Th1 and Th2 cells.[72,73]

## Endocannabinoids

Groups of naturally occurring members of the eicosanoid superfamily that can activate cannabinoid receptors and are derivatives of long-chain fatty acids have been referred to as *endocannabinoids*. They are not stored in cells; rather, they are synthesized rapidly in the manner of PGs and LTs from lipid precursors and are released from—among other cells—cells of the immune system during immune/inflammatory responses. They can then activate cannabinoid receptors on the same or adjacent cells and are metabolized rapidly by the specific serine hydrolase, fatty acid amide hydrolase (FAAH), or by monoglyceride lipase or *N*-acetylethanolamine. Thus inhibition of FAAH offers a strategy for treatment of chronic inflammatory pain.[74] One of the most important endocannabinoids is anandamide (from the Sanskrit word for "bliss"), the amide conjugate of AA and ethanolamine (arachidonoyl ethanolamide; Figure 24-8). Anandamides and other endocannabinoids, such as 2-arachidonylglycerol and virodamine, are involved in a wide range of regulatory functions, including pain perception and modulation of immune responses, actions mediated via cannabinoid 1 (CB1) and CB2 receptor subtypes, resulting in activation of G proteins of the G(i/o) family. Of particular relevance to joint tissue injury is the capacity of anandamide to suppress TNF-induced NF-κB activation by direct inhibition of I-κ-B kinase, an action that is independent of CB1 or CB2 activation.

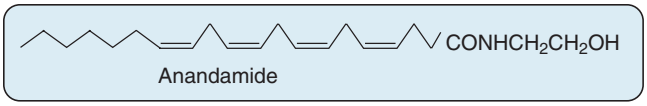

**Figure 24-8** Chemical structure of anandamide (arachidonoyl ethanolamide).

Acid congeners of anandamides are lipoamino acids (elmiric acids) that exist as endogenous substances, regulate tissue levels of anandamide, and exhibit anti-inflammatory effects and the capacity to assist resolution of inflammation. One such compound, *N*-arachidonylglycine (NAGly), is found in many tissues at higher concentrations than anandamide. It has analgesic actions similar to those reported for anandamide but does not exhibit psychotropic action. A library of elmiric acids (n-3 and n-6) has been synthesized. Several of these compounds exhibit anti-inflammatory activity, likely in part by increasing production of $PGJ_2$, and they also modulate immune responses.[75-77] Discovery of naturally occurring and synthetic analogues and metabolites of anandamide suggest that a family of such biologically active substances exists. The polyunsaturated amides dihomo-γ-linolenoyl (20:3 n-6) and adrenoyl (22:4 n-6) ethanolamides have been found in mammalian brain.[78] N-3 fatty acid ethanolamides also exist in mammalian tissues. That anandamide can enhance its own synthesis in macrophages suggests the presence of a rapid response to counter

excessive inflammatory or immune responses. Anandamide is converted by COX-2 (but not by COX-1) into $PGE_2$ or $PGF_{2\alpha}$ ethanolamide directly, without going through free AA.[78] These novel PGs ("prostamides") are pharmacologically active.[79] Because anandamide is a substrate for COX-2, inhibitors of COX-2 may reduce anandamide metabolism, with a subsequent increase in concentration of the anandamide. A combination of anandamide with NSAIDs reduces gastric damage and produces synergistic analgesia in experimental models.[80] NAgly, a naturally occurring lipoamino acid, is also a substrate for COX-2, giving rise to amino acid conjugates of the PGs.[81]

## EICOSANOID RECEPTORS

For many years, it was thought that the lipophilic eicosanoids—in contrast to the peptide molecules for which receptors were characterized routinely—simply "diffused" into cell membranes or were carried in by a binding protein. The isolation and cloning of eicosanoid receptors changed that thinking.[82]

### Prostaglandin Receptors

PGs exert most of their actions through G protein–coupled receptors (GPCRs). Receptors for the COX products are designated P receptors, depending on the prostanoid that has the most affinity for them. These receptors include the PGD receptors (DP); four subtypes of the PGE receptor (EP1 through EP4); the PGF receptor (FP); the $PGI_2$ receptor (IP); and the TX receptor (TP). The IP, DP, EP2, and EP4 receptors mediate increases in cellular cAMP, whereas TP, FP, and EP1 receptors induce calcium mobilization. EP2, EP4, and IP regulate macrophage cytokine production in a similar manner. As might be expected, signaling through these receptors is more complicated. Studies designed to understand $PGE_2$ signaling suggest involvement of phosphatidylinositol-3-kinase (PI3K), mitogen-activated protein kinase (MAPK), and Wnt pathways in EP2R/EP4R regulation of cell growth, migration, and apoptosis.[34] $PGE_2$ is the most abundant of the major eicosanoids in the joint space of patients with RA. The molecular mechanisms whereby $PGE_2$ actions are mediated by each EP subtype have been explained using mice deficient in each subtype.[83] Identification of $PGD_2$ as the ligand for the DP2 receptor led to development of DP2 receptor antagonists for treatment of asthma and airway inflammation.[84]

Modification of immune cell and surrounding cell functions by prostanoids during immune or inflammatory responses is influenced by the different repertoire of PG receptors expressed on these cells. Mice deficient in each EP receptor subtype have been generated, and highly selective agonists for these receptors have been developed. As noted,[34] PGE can suppress or induce bone formation. EP2 and EP4 knockout mice exhibit impaired osteoclastogenesis and inflammation-induced bone resorption. The receptor mediating PGE-induced bone formation is unknown, although it has been proposed that EP2R and EP4R mediate the anabolic effects of $PGE_2$ on bone. In animal models, acute inflammation and pain are completely absent in IP-deficient mice. The profile of PG formation changes as the inflammatory response evolves to a more chronic state, so other receptors are probably involved. It is unlikely that blockade of one receptor will completely block an inflammatory response. More encouraging is the fact that PGs participate in allodynia, a pain response to a usually nonpainful stimulus. Knowing the contribution of P receptors to allodynia should lead to better treatment of neuropathic pain and myofascial pain syndromes such as fibromyalgia.

Stimulation of TX/endoperoxide receptors (TP) elicits platelet aggregation and contraction of vascular smooth muscle and promotes expression of adhesion molecules with subsequent movement of monocytes/macrophages from the circulation to tissue. Thus TP antagonists reduce vascular inflammation, are anti-thrombotic, and maintain vasodilation, actions that mark them as potential agents for treatment of conditions characterized by chronic inflammation.[85]

The availability of cloned P receptors should assist in the development of more effective receptor-active compounds. The $PGI_2$ analogue iloprost is useful for treatment of peripheral vascular disease and pulmonary hypertension. Although iloprost binds to IP with high affinity, it also binds to EP1 and EP3. It may be that targeting activation, blockade, or both of a single P receptor or a specific set of P receptors would provide advantages compared with compounds that work "upstream," such as the COX-2 inhibitors or traditional NSAIDs. For example, it is clear that E prostaglandins are the most important of the endogenous eicosanoids for modulation of the function and mucosal integrity of the gastrointestinal tract. Protection by $PGE_2$ against acid reflux esophagitis and against ethanol- and indomethacin-induced gastric mucosa injury is mimicked by EP1 agonists and attenuated by an EP1 antagonist, whereas EP4 antagonism does not affect the integrity of gastrointestinal mucosa. In addition, $PGE_2$ does not exhibit gastric cytoprotection in EP1 knockout mice. In the small intestine, the protective effect of $PGE_2$ on indomethacin-induced damage is mimicked by both EP3 and EP4 agonists.

Further evidence of the importance of eicosanoids in immune cell function and regulation of immune responses derives from experiments with mice deficient in PG receptors, which indicate that $PGE_2$ assists and amplifies IL-12–mediated Th1 cell differentiation and IL-23–mediated Th17 cell expansion. These $PGE_2$ actions and those of $PGD_2$ and $PGI_2$—also discovered using receptor-deficient mice—contribute to the development of immune diseases.[86] Mice lacking the $PGF_{2\alpha}$ receptor are protected against bleomycin-induced pulmonary fibrosis,[87] a finding with implications for treatment of systemic sclerosis.

The implications for therapy derived from this new knowledge are clear and exciting, but prostanoid analogues with selective binding properties need to be developed. Some progress has been made, and it seems that deletion of P receptors, with the exception of EP4, is not associated with serious problems of fetal development or physiologic function in animals.

### Leukotriene Receptors

Surface receptors for $LTB_4$, denoted BLT1 and BLT2 ($LTB_4$ R-1 and $LTB_4$ R-2), and for the cysteinyl (cys) LTs, produced by cells of the innate immune system, including Th2 lymphocytes, also exert their actions through

transmembrane-spanning GPCRs. High-affinity $LTB_4$ receptors transduce chemotaxis and adhesion responses, whereas low-affinity receptors are responsible for secretion of granule contents and superoxide generation. Recognition that cysLTs are important to the pathogenesis of diseases characterized by acute and chronic inflammation prompted development of selective cysLT receptor antagonists.[88,89] BLT2 knockout mice express normal levels of BLT1 but are protected from development of disease in the K/BxN model of inflammatory arthritis.[90] The COX-1–derived ligand 12(S)-hydroxyheptadeca-5Z,8E,10E-trienoic acid (12-HHT), which is produced during thromboxane synthesis, is an endogenous high-affinity ligand for BLT2 (now called BLT2/HHTR), another example of a connection between the LO and COX pathways. $LTB_4$ in particular among the LTs is involved in development of atherosclerosis, which has emerged as a major concern for patients with inflammatory arthritis and lupus. The receptor for cysLTs includes two subtypes: $CysLT_1$ and $CysLT_2$. The molecular structure of $CysLT_2$ has been constructed. $CysLT_1$ contains 336 amino acid residues, and the gene encoding the receptor is located on the X chromosome. $CysLT_2$ contains 345 amino acids with 40% sequence identity to $CysLT_1$. $CysLT_1$ mediates calcium mobilization and inhibition of adenylate cyclase, whereas $CysLT_2$ mediates calcium mobilization and increased cAMP concentrations. The preferred ligands for $CysLT_1$ are $LTD_4 > LTC_4 > LTE_4$. $CysLT_2$ binds $LTC_4$ and $LTD_4$ equally, whereas $LTE_4$ exhibits low affinity for the receptor. Both receptors have wide tissue and cellular distribution, including a presence in cells that participate in immune responses.[3] Most actions of the cysLTs are mediated by $CysLT_1$. More than a dozen chemically distinct, specific, and selective antagonist drugs that block the binding of LT to $CysLT_1$ have been identified. Clinically, these compounds mainly have been used in the treatment of asthma. Development of selective $LTB_4$ receptor antagonists, which are useful in pre-clinical models, may lead to their use in inflammatory disease.[91] A challenge to the design of "anti-receptor therapy" is the genetic variation in GPCRs that can be associated with disease.[92] Adding to the complexity is the fact that variants may result in altered predisposition to disease, rather than manifestation of the disease. Each variant provides an opportunity to understand receptor function such as recycling or desensitization, thus enhancing the potential for the development of therapy.

## Lipoxin Receptors

LXs can act at their own specific receptors for $LXA_4$ and $LXB_4$, and $LXA_4$ can interact with a subtype of $LTD_4$ receptors. LXs can also act at intra-cellular targets within their cell of origin or after uptake by another cell. The cDNA for the seven-transmembrane-spanning, G protein–coupled $LXA_4$ receptor named ALX/FPR2 (Kd ~ 0.7 nM) has been cloned and characterized. Signaling involves a novel polyisoprenyl-phosphate pathway that regulates phospholipase D.[93] LX actions are cell type specific. The monocyte and neutrophil $LXA_4$ receptors are identical at the cDNA level, but they evoke different responses, and the $LXA_4$ receptor on endothelial cells seems to be a structurally distinct form. $LXA_4$ also binds to the human orphan receptor GPR32, a member of the chemoattractant receptor family. Like $LXA_4$, 15-epi-$LXA_4$ is an anti-inflammatory SPM that binds and activates ALX/FPR2 (Kd ~ 2 nM). Lipoxin $B_4$ ($LXB_4$) and aspirin-triggered 15-epi $LXB_4$ also have anti-inflammatory actions by oral administration and topical application. Stereoselective actions of these compounds indicate they have their own yet-to-be-identified receptors. The resolvins, derived from omega-3 fatty acids, activate the receptors GPR32 and ChemR23.

## Nuclear Receptors

Nuclear receptors are a superfamily of ligand-regulated transcription factors that interact with other transcription factors and with co-regulators that either enhance (co-activators) or inhibit (co-repressors) transcription. The major nuclear receptors involved in regulation of inflammation are the glucocorticoid receptors (GRs), peroxisome proliferator-activated receptors, liver X receptors (LXRs), and the orphan receptor nuclear receptor–related 1 protein (Nurr1). Other members of the nuclear receptor family that contribute to regulation of inflammation include estrogen receptors, vitamin D receptors, and retinoic acid receptors. The clinical efficacy of glucocorticoids is well known, but knowledge of their mechanisms of action has been slow to emerge. The ability of GRs to repress inflammatory responses is due in part to interference with other signal-dependent transcription factors and disruption of activator/co-activator complexes. PPARs are members of the nuclear receptor family of transcription factors, a large and diverse group of proteins that mediate ligand-dependent transcriptional activation and repression. PPARs were first cloned as nuclear receptors that mediate the effects on gene transcription of synthetic compounds called *peroxisome proliferators*. Several mechanisms account for the anti-inflammatory action of PPARγ, including inhibition of NF-κB; inhibition of transcription of genes encoding for chemokines, IL-1β, IL-12, and MMP-9; and promotion of expression of anti-inflammatory mediators, including IL-10 and LXR. PPARγ can be modulated by post-translational modifications (PTMs). Thus regulation of PTMs may be a better approach to disease therapy than the existing PPARγ activators.[94] Interest in PPARs increased dramatically when they were shown to be activated by medically relevant compounds, including NSAIDs and $PGD_2$ and its metabolite 15-deoxy-δ12,14 $PGJ_2$.[95] Most information available on a potential role of PPARs in inflammation relates to PPARγ. One PPARα agonist, palmitoyl ethanolamide, shows promise for relief of chronic pain.[96] PPARα is expressed mainly in tissues that have a high fatty acid catabolism, including liver and the immune system. $LTB_4$ is an activator and natural ligand of PPARα. Activation of PPARα results in induction of genes involved in fatty acid oxidation pathways that degrade fatty acids and derivatives including $LTB_4$. Thus a feedback mechanism that controls inflammation is established. Mechanisms for the anti-inflammatory actions of PPARβ/δ include induction of an anti-inflammatory co-repressor protein, inhibition of NF-κB, and induction of anti-inflammatory mediators. Experiments with PPAR knockout mice indicate that PPARα suppresses $LTB_4$-induced inflammation. PPAR agonists that target PPAR action more selectively are

being developed.[97] Overexpression of Nurr receptors reduces inflammatory cytokine expression, and mutations in the Nurr1 gene are associated with diminished counter-regulation of inflammation.[98]

Several kinases that facilitate co-repressor turnover have been identified. These kinases represent important pharmacologic targets because their inhibition should block gene expression of inflammatory mediators while bypassing the clinically significant adverse events associated with direct targeting of the nuclear receptors. Thus, for example, cartilage matrix degradation is prevented by inhibition of a cyclin-dependent kinase.[98]

## PLATELET-ACTIVATING FACTOR

PAF (1-0-alkyl-2-acetyl-sn-glycero-3-phosphocholine) is a potent mediator of inflammation that causes neutrophil activation, increased vascular permeability, vasodilation, and bronchoconstriction, in addition to platelet activation. PAF is formed by a smaller number of cell types than the eicosanoids, mainly leukocytes, platelets, and endothelial cells. Because of the extensive distribution of these cells, however, the actions of PAF can manifest in virtually every organ system. In contrast to the two long-chain acyl groups present in phosphatidylcholine, PAF contains a long-chain alkyl group joined to the glycerol backbone in an ether linkage at position 1 and an acetyl group at position 2 (Figure 24-9). PAF represents a family of phospholipids (PAF-like lipids: PAF-LL) because the alkyl group at position 1 can vary in length from 12 to 18 carbons. PAF, similar to the eicosanoids, is not stored in cells. Rather, it is synthesized when cells are stimulated, at which time the composition of the alkyl group may change. The immediate effects of PAF are mediated through a cell surface GPCR, PAFR. PAFR is coupled to Gi, Gq, and G12/13. Activation of PAFR results in inhibition of cAMP, mobilization of calcium, and activation of MAPKs, whereas long-term responses depend on intra-cellular receptor activation.[99]

Despite the potent inflammatory effects of PAF, its inhibition in animal models does not lead to marked suppression of inflammatory responses. PAF acetylhydrolase (PAF-AH) circulates in blood in association with lipoproteins, is found in atherosclerotic lesions, and hydrolyzes PAF, and was thus considered to have anti-inflammatory properties and to be a marker for cardiovascular disease. However, PAF-AH also generates compounds that have pro-inflammatory activity, which likely explains why, in three clinical trials, a PAF-AH inhibitor failed to influence C-reactive protein levels, coronary atherosclerosis, or time to cardiovascular death.[100,101] Nonetheless, targeting PAF metabolism, signaling, and the PAF receptor, as monotherapy or with other agents, is a promising approach to suppression of inflammation and carcinogenesis.[102]

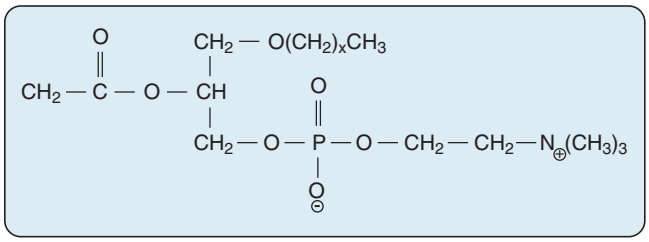

**Figure 24-9** Chemical structure of platelet-activating factor.

## EICOSANOIDS AS REGULATORS OF INFLAMMATION AND IMMUNE RESPONSES

It is clear that in addition to their well-known actions as mediators of inflammation, the stable PGs PGE and $PGI_2$ have anti-inflammatory, inflammatory, and immunomodulatory actions.[103,104] As noted,[68-70] PGJ, LXs, and an array of eicosanoids act as brakes to protect against runaway inflammatory responses. Even $LTB_4$ is capable of modulating inflammation and immune responses.[56] The observations that $PGE_1$ inhibits platelet aggregation and that it suppresses acute and chronic inflammation and joint tissue injury in animal models[105] led to the notion that COX products of AA metabolism might have anti-inflammatory activity. As it became more clear that NSAIDs have anti-inflammatory effects other than interference with COX production and subsequent PG inhibition,[106] consideration was given to the potential protective effects of PGs.

$PGE_1$ has remained an orphan among the eicosanoids, mainly because of a long-held notion that not enough of it is made by human cells to be of use and that its biologic effects are no different from the effects of $PGE_2$ and $PGI_2$. Contrary to popular belief, $PGE_1$ is found in physiologically important amounts in humans. Lost in the vast literature on the "AA cascade" are the early observations of Bygdeman and Samuelsson,[107] who found (using bioassay) that the concentration of $PGE_1$ in human seminal plasma (16 μg/mL) was higher than that of $PGE_2$ (13 μg/mL), $PGE_3$ (3 μg/mL), $PGF_{1\alpha}$ (2 μg/mL), and $PGF_{2\alpha}$ (12 μg/mL). Karim and colleagues[108] found $PGE_1$ to be the sole PGE in human thymus. PG immunoassays usually do not distinguish between $PGE_1$ and $PGE_2$. To identify $PGE_1$, it must first be separated from $PGE_2$ by thin-layer or high-performance liquid chromatography. When such methods have been used, $PGE_1$ has been identified consistently in platelets, leukocytes, macrophages, vas deferens, oviducts, uterus, heart, and skin.[109] Evidence from in vitro and in vivo experiments indicates that PGs, notably PGE compounds, can suppress diverse effector systems of inflammation. PGE can enhance and diminish cellular and humoral immune responses, observations that reinforce a view of these compounds as regulators of cell function. These actions of eicosanoids depend on the stimulus to inflammation, the predominant eicosanoid produced at a particular time in the host response, and the profile of eicosanoid-receptor expression.[110,111]

The "2" series prostaglandins (i.e., E2, D2, and I2) also regulate T cell function and immune responses. $PGE_2$ reduces production of several inflammatory cytokines, including TNF, IFN-γ, and IL-12 and reduces IFN-α production by plasmacytoid dendritic cells (PDCs) from patients with SLE. $PGE_2$-treated PDCs from patients with SLE also induce $CD4^+$ T cell proliferation and skew cytokine production toward a Th2 profile.[112] Another example of an endogenous link between the COX and LO pathways is provided by the observation that $PGE_2$ preserves resolution of inflammation in the murine collagen–induced arthritis model by increasing production of the pro-resolving $LXA_4$.[113]

## MODULATION OF EICOSANOID SYNTHESIS BY ADMINISTRATION OF PRECURSOR FATTY ACIDS

The relationship between essential fatty acids and PGs was discovered simultaneously and independently by van Dorp and colleagues[114] and Bergstrom and colleagues.[115] Both groups reported that AA was converted to $PGE_2$, and shortly thereafter they showed that $PGE_1$ is formed from DGLA.[116] Attempts to modify eicosanoid production have been directed at providing fatty acids other than AA as substrates for oxygenation enzymes in an effort to generate a unique eicosanoid profile with immunosuppressive and anti-inflammatory effects.[63,117] The fatty acids themselves, by virtue of their incorporation into signal-transduction elements, also have effects that are independent of eicosanoid effects on cells involved in inflammation and immune responses.[118]

Experiments directed at suppression of TX synthesis, enhancement of PGI production, and inhibition of platelet aggregation have been done in an effort to limit inflammatory responses. EPA is not found in appreciable amounts in cells from persons who eat a Western-style diet. Fish oil lipids, which are rich in EPA (20:5 n-3), inhibit formation of COX products (e.g., $TXA_2$ and $PGE_2$) derived from AA, and the newly formed $TXA_3$ has much less ability than $TXA_2$ to constrict vessels and aggregate platelets. Production of $PGI_2$ (prostacyclin) by endothelial cells is not reduced appreciably by increased EPA content, and the physiologic activity of newly synthesized $PGI_3$ is added to that of $PGI_2$. Administration of fish oil to humans leads to reduced production of $LTB_4$ by means of 5-LO in stimulated neutrophils and monocytes and induces EPA-derived $LTB_5$, which is far less biologically active than $LTB_4$. Fish oil also reduces production of IL-1β, TNF, and PAF by activated blood monocytes. In randomized controlled trials of administration of fish oil to patients with RA, tender joint counts and duration of morning stiffness are reduced, and use of NSAIDs is decreased. Fish oil treatment of patients with early RA (<12 months) reduces the triple disease-modifying anti-rheumatic drug (DMARD) failure rate and increases the American College of Rheumatology (ACR) remission rate.[119] Because NSAIDs confer an increased risk for cardiovascular disease and increased mortality from cardiovascular disease occurs in patients with RA, an added benefit of fish oil for patients with RA may be reduced risk of cardiovascular disease directly and by virtue of less use of NSAIDs.[120] Another potential benefit of an increase in dietary omega-3 fatty acids might be greater formation, from EPA and DHA, of resolvins, protectins, and maresins, all of which participate in resolution of inflammation.[66,68-70]

The other "alternative" eicosanoid precursor fatty acid, DGLA (20:3 n-6), is also increased by administration of certain plant seed oils, notably oils extracted from the seeds of *Oenothera biennis* (evening primrose) and *Boragio officinalis* (borage), which contain relatively large amounts of GLA. GLA is converted to DGLA, the immediate precursor of $PGE_1$, an eicosanoid with known anti-inflammatory and immunoregulating properties.[103] Administration of GLA to volunteers and patients with RA results in increased production of $PGE_1$ and reduced production of the inflammatory eicosanoids $PGE_2$, $LTB_4$, and $LTC_4$ by stimulated peripheral blood monocytes. In addition to competing with AA for oxidative enzymes, DGLA cannot be converted to inflammatory LTs. Rather, it is converted by means of 15-LO to a 15-hydroxy-DGLA, which has the capacity to inhibit 5-LO and 12-LO activities. DGLA should have anti-inflammatory actions because of its capacity to reduce synthesis of oxygenation products of AA through the COX and LO pathways.[117,121]

In addition to their roles as precursors of eicosanoids, essential fatty acids are important for maintenance of cell membrane structure and function, and they protect the gastric mucosa from NSAID-induced injury. DGLA can also modulate immune responses in an eicosanoid-independent manner. DGLA suppresses IL-2 production by human peripheral blood monocytes in vitro, suppresses proliferation of IL-2–dependent human peripheral blood and synovial tissue T lymphocytes, and reduces expression of activation markers on T lymphocytes directly in a manner that is independent of its conversion to eicosanoids. Oral administration of oils enriched in GLA, but not administration of oils enriched in linoleic acid (the parent n-6 fatty acid) or α-linolenic acid (the parent n-3 fatty acid), reduces proliferation of human lymphocytes activated through the T cell receptor complex.[122]

Addition of GLA to peripheral blood mononuclear cells in vitro or oral administration of GLA to volunteers reduces production of IL-1β and TNF from stimulated cells and reduces autoinduction of IL-1β, preserving the protective effects of IL-1β, while suppressing excessive production of the cytokine.[123] GLA suppresses acute and chronic inflammation, including arthritis, in several animal models, and randomized, double-blind, placebo-controlled trials of GLA in patients with RA and active synovitis indicate that GLA treatment results in statistically significant and clinically relevant reduction in signs and symptoms of disease activity compared with baseline and placebo. GLA also reduces the need for NSAID and corticosteroid therapy.[124,125]

EPA suppresses conversion of DGLA to AA, and a combination of EPA-enriched and GLA-enriched oils exhibits synergy in its capacity to reduce the reduction of synovitis in animal models.[126] In addition, administration of black currant seed oil, which contains the n-3 fatty acid α-linolenic acid (which is converted to EPA) and the n-6 GLA, suppresses active synovitis in patients with RA.[127] The synergy observed in the animal models was not reprised in an 18-month double-blind trial of a combination of fish oil and borage oil in patients with RA. However, treatment with each oil alone and with the combination resulted in meaningful clinical responses, including a reduction in DMARD therapy greater than that seen in matched patients from an RA registry. In addition, all three treatment groups exhibited significantly reduced total and low-density lipoprotein cholesterol and triglycerides, increased high-density lipoprotein cholesterol, and an improved plasma atherogenic index.[128,129] Much larger amounts of the polyunsaturated fatty acids (GLA, EPA, and DHA) can be delivered in far smaller capsules than are needed to accommodate the natural oils, a strategy that should be adopted to improve compliance.

CHAPTER 25

# Cell Recruitment and Angiogenesis

Zoltán Szekanecz • Alisa E. Koch

**KEY POINTS**

- Leukocyte recruitment into tissues through the vessel wall into the synovium is a crucial process in the pathogenesis of inflammatory diseases.
- Several classes of cell adhesion molecules are involved in leukocyte extravasation.
- Chemokines and their receptors stimulate chemotaxis of neutrophils, lymphocytes, and monocytes into tissues.
- Angiogenesis, the formation of new vessels, is involved in inflammation and tumor progression.
- A number of soluble and cell-bound factors, including chemokines and adhesion receptors, may stimulate or inhibit angiogenesis.
- Specific targeting of leukocyte adhesion, chemokines, and/or angiogenesis might be useful for the future management of rheumatic diseases; however, clinical trials have primarily had negative or mixed results to date.

Inflammatory leukocytes, endothelial cells (ECs), synovial fibroblasts, as well as soluble mediators and cell surface–bound adhesion molecules (CAM), are involved in cell trafficking in inflammatory rheumatic diseases[1-6] (Figure 25-1). Leukocyte entry into inflamed tissues occurs by leukocyte adhesion to ECs, followed by transendothelial migration.[3-6] Transendothelial migration or diapedesis may be the point of no return during the inflammatory response.[6] The chemotaxis of inflammatory cells is mainly regulated by chemokines and their receptors.[7-11] The formation of new capillaries from pre-existing vessels, termed *angiogenesis*, is a key event underlying inflammation that perpetuates leukocyte adhesion and migration.[8,12-18] On the other hand, new vessel formation from endothelial progenitor cells (EPCs), termed *vasculogenesis*, is impaired in inflammatory arthritides.[16-20] Inflammatory sites contain an existing network of cells, CAMs, chemokines, and angiogenic factors. Rheumatoid arthritis (RA) is an excellent prototype of chronic inflammatory diseases; thus the inflammatory processes previously described will be discussed mainly in light of the data obtained from the study of this disease. First, the key characteristics of endothelial biology, CAMs, chemokines, angiogenesis, and vasculogenesis will be presented, followed by a description of leukocyte trafficking. Next, the targeting of CAMs, chemokines, and neovascularization will be discussed.

## ENDOTHELIAL PATHOPHYSIOLOGY IN INFLAMMATION

### Endothelial Permeability

ECs line the lumina of blood vessels, and thus they separate and connect the blood and the extra-cellular matrix (ECM) of the vessel wall. The endothelium is involved in numerous homeostatic mechanisms, as well as in pathologic states such as inflammation.[21-24]

ECs express a variety of cell surface molecules and synthesize and release soluble mediators. In inflammatory states, such as arthritis, ECs interact with other cell types, including leukocytes, fibroblasts, and smooth muscle cells. ECs express numerous CAMs, adhere to ECM components, secrete a number of inflammatory mediators, such as cytokines, nitric oxide (NO), prostaglandins, endothelin 1 (ET-1), and proteases, and thus regulate inflammation in the surrounding tissue. On the other hand, ECs are active responders to external stimuli because they may become targets of inflammatory mediators produced by leukocytes.[21-23,25-30]

Under inflammatory conditions, the vascular endothelium undergoes morphologic changes that include vasodilatation and increased permeability (leakage). These morphologic alterations may result from several mechanisms, including EC contraction and retraction, leukocyte- or anti-EC antibody (AECA)-mediated vascular injury and regeneration.[21,26,31,32] ECs and leukocytes release vasodilatory mediators, including prostacyclin ($PGI_2$), NO, and platelet-activating factor (PAF).[21,22,27,33] Factors that trigger endothelial leakage include, among others, histamine, serotonin, complement factors, bradykinin, leukotrienes, PAF, and AECA. EC adhesion, accompanied by cytoskeletal reorganization, occurs upon EC activation by pro-inflammatory cytokines, such as interleukin (IL)-1, tumor necrosis factor (TNF) or interferon (IFN)-γ.[21,33-35]

### Endothelial Injury and Regeneration

In inflammatory states, endothelial injury is caused by inflammatory cells, as well as soluble mediators.[23,36-38]

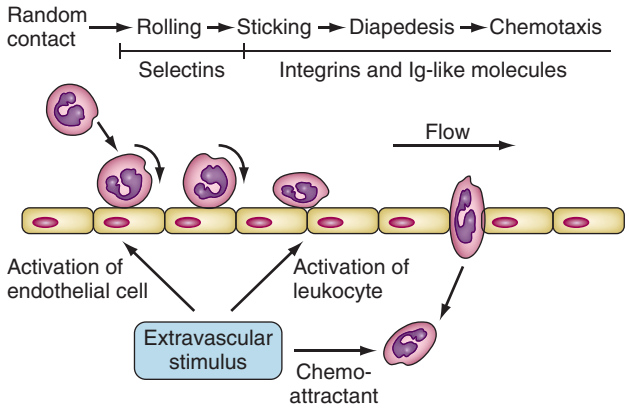

**Figure 25-1** The process of leukocyte extravasation into the synovium. Ig, Immunoglobulin.

Leukocyte-EC interactions, described later in more detail, may cause EC injury and thus increased vascular leakage. EC injury primarily involves reactive oxygen intermediates (ROI) and matrix metalloproteinase (MMP) enzymes produced by inflammatory leukocytes.[23-25,38,39] In addition to leukocytes, various mediators produced by ECs themselves and other cells lead to endothelial injury. ECs synthesize NO, prostaglandins, ET-1, and other substances.[21-23,28,30,39,40] During inflammation, ECs and leukocytes produce high amounts of NO,[23,41] and NO interacts with ROI.[23,39,40] Asymmetric dimethylarginine (ADMA) is a naturally produced amino acid that circulates in the plasma. Increased ADMA production has been associated with both vascular injury and inflammatory rheumatic diseases.[23,40,42,43] ET-1, a vasoconstrictor peptide, activates leukocyte adhesion and is also involved in ECM remodeling and vascular injury.[23,44]

Vascular regeneration occurring after inflammatory injury is linked to EPCs and vasculogenesis and therefore will be discussed later in this chapter. Apart from naturally occurring processes that lead to regeneration, there have been several attempts to prevent endothelial injury, among others, by organic nitrates (isosorbide-dinitrate and isosorbid-mononitrate) that increase NO production, thrombomodulin, tissue factor, prostacyclin (PGI), adiponectin, sirtuins (Sirt-1), or ligustrazine.[45]

## CELL ADHESION MOLECULES

CAMs are involved in cell adhesion and migration underlying inflammation, malignancies, tissue development, and repair. CAMs have been classified into integrin, selectin, immunoglobulin (Ig), and cadherin superfamilies based on their structural features[3,4,6,46] (Table 25-1).

### Integrins

Integrins are αβ heterodimers, in which each of the common β chains is associated with one or more α subunits.[46,47] Cell adhesion to ECM is mostly mediated by $\beta_1$ and $\beta_3$, whereas intercellular adhesion is facilitated through $\beta_1$ and $\beta_2$ integrins.[2,46,47] $\beta_1$ and $\beta_3$ integrins are expressed on ECs, whereas $\beta_2$ integrins are leukocyte CAMs.[47] The $\alpha_1$-$\alpha_6$, $\alpha_V$, $\alpha_L$, $\alpha_M$, $\alpha_X$, and $\beta_1$-$\beta_7$ integrin subunits have all been detected in RA.[3-5,48] Only the most important integrins will be discussed further.

Among $\beta_1$ integrins, the $\alpha_4\beta_1$ heterodimer, also known as very late antigen 4 (VLA-4), plays an important role in lymphocyte-endothelial interactions. This molecule recognizes at least two alternative ligands, such as vascular cell adhesion molecule-1 (VCAM-1), a member of the Ig superfamily, and the CS-1 region of fibronectin. $\alpha_4\beta_1$ is present on mononuclear leukocytes.[3,46,47] The $\alpha_4\beta_1$ integrin, as well as VCAM-1 and CS-1 are expressed on various cell types within the RA synovium.[3,4] Other $\beta_1$ integrins also exert increased expression on lymphocytes under inflammatory conditions.[3,4,48] For example, synovial lining cells also express the $\beta_1$ integrin subunit, whereas ECs express $\alpha_1\beta_1$, $\alpha_3\beta_1$, and $\alpha_5\beta_1$.[3]

All members of the $\beta_2$ (leukocyte) integrin family, namely, the lymphocyte function-associated antigen 1 (LFA-1) ($\alpha_L\beta_2$ dimer), the Mac-1 ($\alpha_M\beta_2$), and the p150,95

**TABLE 25-1** Some Relevant Adhesion Receptor-Ligand Pairs in Inflammation

| Adhesion Receptors | Ligands |
|---|---|
| **Integrins** | |
| $\alpha_1\beta_1$ (VLA-1) | Laminin, collagen |
| $\alpha_2\beta_1$ (VLA-2) | Laminin, collagen |
| $\alpha_3\beta_1$ (VLA-3) | Laminin, collagen, fibronectin |
| $\alpha_4\beta_1$ (VLA-4) | Fibronectin, VCAM-1 |
| $\alpha_5\beta_1$ (VLA-5) | Fibronectin |
| $\alpha_6\beta_1$ (VLA-6) | Laminin |
| $\alpha_L\beta_2$ (LFA-1, CD11a/CD18) | ICAM-1, ICAM-2, ICAM-3, JAM-A |
| $\alpha_M\beta_2$ (Mac-1, CD11b/CD18) | ICAM-2, iC3b |
| $\alpha_X\beta_2$ (CD11c/CD18) | iC3b, fibrinogen |
| $\alpha_E\beta_7$ | E-cadherin |
| $\alpha_4\beta_7$ | Fibronectin, VCAM-1, MadCAM-1 |
| **Immunoglobulin Superfamily** | |
| ICAM-1 (CD54) | LFA-1, Mac-1 |
| ICAM-2 | LFA-1 |
| ICAM-3 | LFA-1 |
| VCAM-1 | $\alpha_4\beta_1$, $\alpha_4\beta_7$ |
| MadCAM-1 | $\alpha_4\beta_7$, L-selectin |
| CD2 | LFA-3 |
| PECAM-1 (CD31) | PECAM-1, $\alpha_V\beta_3$ |
| **Selectins** | |
| L-selectin (CD62L, LAM-1) | Sialylated carbohydrates, GlyCAM-1 |
| E-selectin (CD62E, ELAM-1) | ESGL (Sialyl-Lewis-X) |
| P-selectin (CD62P) | PSGL (sialyl-Lewis-X, other carbohydrates) |
| **Cadherins** | |
| E-cadherin (Cadherin-1) | E-cadherin |
| N-cadherin (Cadherin-2) | N-cadherin |
| Cadherin-11 | Cadherin-11 |
| **Others** | |
| CD44 | Hyaluronic acid, fibronectin |
| Endoglin | TGF-β1, TGF-β3 |
| JAMs | JAMs |

ELAM, Endothelial leukocyte adhesion molecule; ESGL, E-selectin glycoprotein ligand; GlyCam, glycosylation-dependent cell adhesion molecule; ICAM, intercellular adhesion molecule); JAM-A, junctional adhesion molecule-A; LAM, leukocyte adhesion molecule; LFA, lymphocyte function–associated antigen; Mac-1, macrophage antigen-1; MadCAM, mucosal addressin cell adhesion molecule; PECAM, platelet-endothelial adhesion molecule; PSGL, P-selectin ligand; TGF, transforming growth factor; VLA, very late antigen; VCAM, vascular cell adhesion molecule.

($\alpha_X\beta_2$) molecules are present on neutrophils and monocytes. In contrast, only LFA-1 is present on lymphocytes. All three intercellular adhesion molecule (ICAM) ligands for LFA-1, namely ICAM-1, ICAM-2, and ICAM-3 belong to the Ig superfamily. Mac-1 binds ICAM-1 and some non-CAM ligands. All $\beta_2$ integrins are expressed on synovial leukocytes.[3-5]

The $\beta_3$ integrins (gpIIb/IIIa molecule, $\alpha_g$pIIb$\beta_3$, and the vitronectin receptor, $\alpha_V\beta_3$) have been detected on macrophages, lining cells, and fibroblasts in the RA synovium.[3,48] Among other integrins containing the $\alpha_V$ subunit, the fibronectin-vitronectin receptor $\alpha_V\beta_5$ is expressed by most, whereas $\alpha_V\beta_1$ and $\alpha_V\beta_3$ have been detected on some synovial lining cells. Their ligands, fibronectin and vitronectin are also present in the synovial lining layer.[3,48] Another $\alpha_4$ subunit–containing integrin, $\alpha_4\beta_7$, also binds to VCAM-1 and the CS-1 peptide.[47] The $\alpha_4\beta_7$ integrin is highly expressed in tissues belonging to the mucosa-associated lymphoid tissue (MALT), such as the gut and skin, as well as the synovium. Therefore this integrin may link arthritis to inflammatory bowel disease or psoriasis.[49]

## Immunoglobulin Superfamily Members

The Ig superfamily is a group of transmembrane glycoproteins that contain one or more Ig-like motifs.[46,47] VCAM-1, already mentioned previously, is constitutively expressed on ECs, however, its expression is upregulated by pro-inflammatory cytokines.[3,46] There is abundant VCAM-1 expression in the inflamed synovium.[3-5]

ICAM-1, the counter-receptor for the $\beta_2$ integrins, is expressed on both EC and leukocytes.[3,46,47,50] ICAM-2 is constitutively expressed on EC and may not be involved in inflammatory transendothelial migration.[50] ICAM-3 is a leukocyte CAM; however, it is also present on some ECs.[50] ICAM-1 and ICAM-3 expression is upregulated under inflammatory conditions, such as in RA.[3,4,50] Both ICAM-1 and VCAM-1 are clustered to the front of the cell membrane during diapedesis. Actin-rich docking structures are formed before transendothelial migration.[6]

Other members of the Ig superfamily include CD2 and LFA-3. These CAMs bind to each other.[3,46,47] Although CD2 is a T cell marker, LFA-3 is present on ECs and synovial lining cells, as well as macrophages and fibroblasts.[3,4]

Platelet-endothelial adhesion molecule 1 (PECAM-1) mediates homotypic adhesion by binding to another PECAM-1, as well as heterotypic adhesion by recognizing the $\alpha_V\beta_3$ integrin.[3,46,51] PECAM-1 is a marker of ECs,[46,51] and its expression is upregulated on RA synovial lining cells and interstitial macrophages.[3,48,51]

Interestingly, some sialylated and glycosylated CAMs, also known as tumor-associated antigens, such as members of the carcinoembryonic antigen (CD66) family, also belong to the Ig superfamily. Structurally, CD66a-e molecules are closely related to PECAM-1 and CD66. Similar to PECAM-1, these molecules exert abundant expression on myeloid cells in the RA synovium.[1,3]

## Selectins

Selectins contain a lectin-like extra-cellular N-terminal domain, an epidermal growth factor (EGF)-like motif, and two to nine moieties related to complement regulatory proteins.[47,52] E- and P-selectin are expressed by ECs, whereas L-selectin is mostly expressed by leukocytes.[52] E-selectin is a marker for cytokine-induced EC activation.[52] E-selectin ligand-1 (ESL-1) and P-selectin ligand-1 (PSGL-1) contain sialylated glycan motifs such as sialyl Lewis-X ($sLe^x$).[52] P-selectin is constitutively present on the membrane of EC Weibel-Palade bodies.[52] L-selectin serves as a lymphocyte homing receptor, where it mediates the physiologic recirculation of naïve lymphocytes through specialized high-endothelial venules (HEVs).[46,52] However, L-selectin is also involved in inflammatory leukocyte recruitment.[3,52]

Increased expression of E- and P-selectin occurs in RA compared with noninflamed synovial ECs. Whereas E- and P-selectin can be induced upon EC activation, the cellular expression of L-selectin is decreased by shedding after cytokine treatment.[3,4,48,53]

## Cadherins

Cadherins are calcium-dependent CAMs. N-, P- and E-cadherin are primarily involved in embryogenesis and tissue development; however, synovial fibroblast cadherin-11 has been implicated in arthritis as well.[3,4,46,47]

## Other Adhesion Receptors

CD44 exerts a proteoglycan-like structure. It is a receptor for hyaluronate and is expressed on activated ECs in inflammatory sites.[3,4,46,48,53,54] CD44 is present on most synovial lymphocytes, as well as lining cells, leukocytes, ECs, and fibroblasts.[3,4,53]

Vascular adhesion protein 1 (VAP-1) is isolated from synovial ECs. VAP-1 is a marker of activated endothelium, because its expression is increased in inflammation.[55]

Endoglin has been identified as a receptor for transforming growth factors (TGF)-β1 and -β3. This molecule contains the RGD (arginine-glycine-aspartate) sequence, a motif found in a number of ECM ligands for integrins. Thus endoglin may be involved in intercellular adhesion. Endoglin was detected on most ECs; however, endoglin expression is increased on RA synovial lining cells and macrophages.[1,3]

Junctional cell adhesion molecules (JAMs) are also involved in transendothelial migration of leukocytes. JAM-A and JAM-C have been implicated in adhesive events underlying inflammatory conditions, such as RA.[2,6,56]

Other CAMs involved in leukocyte transendothelial migration in various inflammatory conditions include poliovirus receptor (CD155), MUC18 (CD146), CD166, and integrin-associated protein (CD47).[6,57-59]

# CHEMOKINES AND CHEMOKINE RECEPTORS

## Chemokine Superfamilies and Their Receptors

Chemokines have been classified into the CXC, CC, C, and $CX_3C$ supergene families.[60-63] The traditional names of chemokines have been replaced by a unique designation of CXCL, CCL, XCL and $CX_3CL$, considering all chemokines as ligands of their respective receptors.[61-63] In CXC

chemokines, two conserved C residues are separated by one unconserved amino acid. These mediators chemoattract neutrophils, lymphocytes, and monocytes. The underlying molecular mechanisms include leukocyte integrin expression and L-selectin shedding, cytoskeletal reorganization, neutrophil degranulation, and phagocytosis, as well as the production of MMPs and other inflammatory mediators.[10,11,61,62,64] CC chemokines include two adjacent C residues in their structure. These CC chemokines are chemotactic for monocytes and lymphocytes.[61-63] The C chemokine family contains two members, XCL1 (lymphotactin), and XCL2 (single C motif 1β; SCM-1β). The single member of the $CX_3C$ family is $CX_3CL1$ (fractalkine). This chemokine is chemotactic for mononuclear cells, mediates T cell adhesion and cytokine production, regulates the cytoskeletal structure, proliferation, and migration of synovial fibroblasts. $CX_3CL1$ is also an angiogenic mediator[65,66] (Table 25-2).

Chemokine receptors have seven transmembrane domains and are expressed on target cells. They have been termed *CXCR*, *CCR*, *CR*, and *$CX_3CR$*.[60-63] Some chemokine receptors, such as CXCR2, CCR1, CCR2, CCR3, or CCR5 have multiple ligands, whereas others, including CXCR4, CXCR5, CXCR6, CCR8, or CCR9, are specific receptors for one single ligand[10,11,61] (see Table 25-2).

## CXC Chemokines in Arthritis

The most relevant CXC chemokines involved in the pathogenesis of arthritis are CXCL1 (groα), CXCL4 (platelet factor 4; PF4), CXCL5 (epithelial cell–derived neutrophil attractant 78; ENA-78), CXCL6 (granulocyte chemotactic protein 2; GCP-2), CXCL7 (connective tissue–activating protein III; CTAP-III), CXCL8 (IL-8), CXCL9 (Mig), CXCL10 (IFN-γ–inducible 10 kDa protein; IP-10), CXCL12 (stromal cell–derived factor 1; SDF-1), CXCL13 (B cell–activating chemokine 1; BCA-1), and CXCL16. All are abundantly expressed in the sera, synovial fluids, and tissues of RA patients.[60,67]

During the last decade, it has become clear that anti-citrullinated peptide antibodies (ACPA) are a harbinger of RA.[68,69] Given this important finding, we have recently shown that alteration of just one amino acid from arginine to citrulline in CXCL5 (ENA-78) changes its function from a nonmonocyte-recruiting to a monocyte-recruiting chemokine.[70]

Synovial macrophages are the major source of most CXC chemokines.[67,71] CXCL12, 13, and 16 are more peculiar CXC chemokines in many ways. First, although the other CXC chemokines described previously have common receptors, CXCL12, 13, and 16 are specific ligands for CXCR4, 5, and 6, respectively.[67,71] CXCL12 promotes angiogenesis despite lacking the glutamyl-leucyl-arginyl (ELR) motif, which is usually required for this function.[8,72,73] CXCL12 induces CXCR4-dependent integrin-mediated lymphocyte and monocyte adhesion and migration, as well as osteoclastogenesis, bone resorption, and thus radiographic progression in RA.[74-80] CXCL13 is also expressed by synovial fibroblasts, T cells, and ECs in RA.[81,82] CXCL16 is secreted by synovial macrophages and fibroblasts and is involved in mononuclear cell recruitment into the RA synovium.[83-86]

**TABLE 25-2** Chemokines and Chemokine Receptors Relevant for Arthritis

| Chemokine Receptor | Chemokine Ligand |
|---|---|
| **CXC Chemokine Receptors** | |
| CXCR1 | CXCL8, CXCL6 |
| CXCR2 | CXCL8, CXCL5, CXCL1, CXCL7, CXCL6 |
| CXCR3 | CXCL10, CXCL4, CXCL9 |
| CXCR4 | CXCL12 |
| CXCR5 | CXCL13 |
| CXCR6 | CXCL16 |
| CXCR7 | CXCL11, CXCL12 |
| **CC Chemokine Receptors** | |
| CCR1 | CCL3, CCL5, CCL7, CCL14, CCL15, CCL16 |
| CCR2 | CCL2, CCL7, CCL16 |
| CCR3 | CCL5, CCL8, CCL7, CCL15 |
| CCR4 | CCL17, CKLF1 |
| CCR5 | CCL3, CCL5, CCL8, CCL14 |
| CCR6 | CCL20 |
| CCR7 | CCL21 |
| **C Chemokine Receptors** | |
| XCR1 | XCL1 |
| **C-X3-C Chemokine Receptors** | |
| CX3CR1 | CX3CL1 |

Chemokines are classified according to the positions of the first two cysteines (C) of the four conserved N-terminal cysteines: CC chemokine ligand (CCL), first two cysteines are adjacent; CXC chemokine ligand (CXCL), first two cysteines are separated by amino acid X other than cysteine; CCR, CC chemokine receptor; CXCR, CXC chemokine receptor.

## CC Chemokines in Rheumatoid Arthritis

CCL2 (monocyte chemotactic protein [MCP]-1), CCL3 (macrophage inflammatory protein 1; MIP-1α), CCL5 (Regulated upon Activation, Normal T cell Expressed and Secreted [RANTES]), CCL7 (MCP-3), CCL8 (MCP-2), CCL13 (MCP-4), CCL14 (hemofiltrate CC chemokine [HCC]-1), CCL15 (HCC-2), CCL16 (HCC-3), CCL17 (thymus- and activation-regulated chemokine; TARC), CCL18 (PARC), CCL19 (EBL-1–ligand chemokine [ELC]), CCL20 (MIP-3α), and CCL21 (synovial lining cells [SLC]) have all been detected in RA sera and synovia.[67,71,87]

Among these chemokines, CCL20 preferentially recruits Th17 cells,[88] induces both osteoblast proliferation and osteoclast differentiation, and collaborates with the RANK ligand system in the uncoupling between new bone formation and bone resorption in RA.[89,90] CCL13 has been associated with the RA cartilage and is released by articular chondrocytes.[91,92]

## C and $CX_3C$ Chemokines in Rheumatoid Arthritis

XCL1 (lymphotactin) is involved in T cell accumulation in the joint affected with RA.[93,94] CX3CL1 expression is upregulated in the joint affected with RA.[65] This chemokine has also been associated with accelerated atherosclerosis that leads to increased cardiovascular morbidity in RA.[66,95]

## Chemokine Receptors in Arthritis

In general, most CXCRs have been implicated in the pathogenesis of arthritis. CXCR1 and CXCR2 are the most

relevant inflammatory and angiogenic CXC chemokines described previously.[10,61,96] CXCR3 may be the most important receptor in leukocyte homing into Th1-type inflammatory sites, such as the RA synovium.[97,98] CXCR4 is involved in CXCL12-dependent lymphocyte migration.[78] CXCR4, CXCR5, and CXCR6 are involved in synovial lymphoid neogenesis.[8,87]

Among CCRs, CCR1, 2, 3, 4, 5, 6, and 7 are abundantly expressed in the RA synovium and on synovial cells.[8,67] CCR5 may be the most prominent CCR to characterize Th1 inflammatory infiltrates.[98,99] In some studies, a single nucleotide polymorphism leading to the production of the truncated Δ32-CCR5 nonfunctional receptor allele was found to protect against RA.[100-103] CCR6 is involved in the ingress of Th17 lymphocytes into the joint.[88,104] CCR7 has been associated with synovial lymphoid neogenesis.[105]

XCR1 is expressed on RA synovial lymphocytes, macrophages, and fibroblasts, whereas $CX_3CR1$ has been detected on macrophages and dendritic cells.[61,65,106] $CX_3CR1$ has been implicated in the recruitment of Th1-type lymphocytes into the joint.[106]

## ANGIOGENESIS IN INFLAMMATION

### Angiogenic Process

Synovial angiogenesis is a cascade of multiple events in which new capillaries develop from existing blood vessels. First, angiogenic mediators, which are described later in the text, activate ECs. This activation is associated with the production of proteases. These enzymes degrade the EC basement membrane and the ECM, thus enabling endothelial outgrowth. The migration of loose ECs results in the formation of capillary sprouts; followed by lumen formation within the sprout. Two sprouts anastomose with each other, thus forming capillary loops. New basement membrane is then synthesized. The continuous emigration of ECs results in further generation of new vessels. The outcome of angiogenesis is based upon the imbalance between angiogenic mediators and angiostatic factors described later in the text.[14,107-110]

### Mediators of Angiogenesis in Rheumatoid Arthritis

Several cytokines, growth factors, chemokines and their receptors, certain CAMs, as well as other mediators, can modulate neovascularization in RA[1,14-16,109,110] (Table 25-3).

Among growth factors, vascular endothelial growth factor (VEGF) and the hypoxia-hypoxia–inducible factor (HIF)–VEGF-angiopoietin (Ang)/Tie axis are of outstanding importance in RA-associated angiogenesis (Figure 25-2). VEGF is induced by hypoxia and HIFs (HIF-1 and HIF-2) in RA. Significant hypoxia is characteristic of RA joints. This low oxygen tension has been associated with inflammatory activity and increased expression of angiogenic VEGF. Hypoxia enables the outgrowth of immature, unstable vessels. HIFs are the master regulators of the adaptive responses to hypoxia. HIF is a heterodimeric transcription factor composed of HIF-α and HIF-β. The VEGF gene that contains hypoxia responsive elements (HRE), is a target for HIFs. High oxygen tension leads to hydroxylation and thus degradation of HIF-α, whereas hypoxia inhibits HIF hydroxylation, allowing HIF-1α stabilization and dimerization with HIF-1β (see Figure 25-2). However, hypoxia may also act via HIF-independent regulatory pathways, including peroxisome proliferator-activated receptors (PPAR). The Ang1/Tie2 complex interacts with VEGF during the stabilization of newly formed blood vessels. In contrast, Ang2, an antagonist of Ang1, inhibits vessel maturation. VEGF, HIF-1α, HIF-2α, Ang1, and Tie2 have been detected in the RA synovium even in the very early phase of the disease. Toll-like receptors (TLR) such as TLR2 may also induce VEGF-dependent angiogenesis, and this is mediated through Tie2 signaling in RA.[111] Survivin, an apoptosis inhibitor, is also involved in VEGF-dependent angiogenesis. Hypoxia also stimulates the production of CXCL12 (a major angiogenic chemokine described previously) by RA synovial fibroblasts.[14,112-117] Other angiogenic mediators, such as IL-6, IL-17, IL-18, nitric oxide (NO), monocyte/macrophage migration inhibitory factor (MIF), ET-1, and others may also stimulate angiogenesis via VEGF-dependent mechanisms.[14,112,115]

Placenta growth factor (PIGF) is a member of the VEGF family, and this mediator also binds to the VEGF receptor. There is abundant expression of PIGF in the arthritic synovial tissue. Other growth factors, including fibroblast (FGF-1

**TABLE 25-3** Some Angiogenic and Angiostatic Factors in Rheumatoid Arthritis

| | Mediators | Inhibitors |
|---|---|---|
| Chemokines | CXCL1, CXCL5, CXCL7, CXCL8, CXCL12, CCL2, CCL21, CCL23, CX3CL1 | CXCL4, CXCL9, CXCL10, CCL21 |
| Matrix molecules | Type I collagen, fibronectin, laminin, heparin, heparan sulphate | Thrombospondin, RGD sequence |
| Cell adhesion molecules | $\beta_1$ and $\beta_3$ integrins, E-selectin, P-selectin, CD34, VCAM-1, endoglin, PECAM-1, VE-cadherin, $Le^y$/H, MUC18 | RGD sequence (integrin ligand) |
| Growth factors | VEGF, bFGF, aFGF, PDGF, EGF, IGF-I, HIF-1, TGF-β* | TGF-β* |
| Cytokines | TNF, IL-6, IL-15, IL-18 | IL-4, IL-6,* IFN-α, IFN-γ |
| Proteases | MMPs, plasminogen activators | TIMPs, plasminogen activator inhibitors |
| Others | Angiogenin, substance P, prolactin | DMARDs, infliximab, etanercept, angiostatin, endostatin |

*Mediators with both proangiogenic and antiangiogenic effects.
aFGF, Acidic fibroblast growth factor; bFGF, basic fibroblast growth factor; DMARDs, disease-modifying anti-rheumatic drug; EGF, endothelial growth factor; HIF-1, hypoxia-inducible factor-1; IFN, interferon; IGF, insulin-like growth factor; IL, interleukin; MMPs, matrix metalloproteinases; MUC18, mucin-like protein 18; PDGF, platelet-derived growth factor; PECAM, platelet-endothelial adhesion molecule; RGD, arginine-glycine-aspartate; TGF, transforming growth factor; TIMPs, tissue inhibitors of metalloproteinase; TNF, tumor necrosis factor; VCAM, vascular cell adhesion molecule; VEGF, vascular endothelial growth factor.

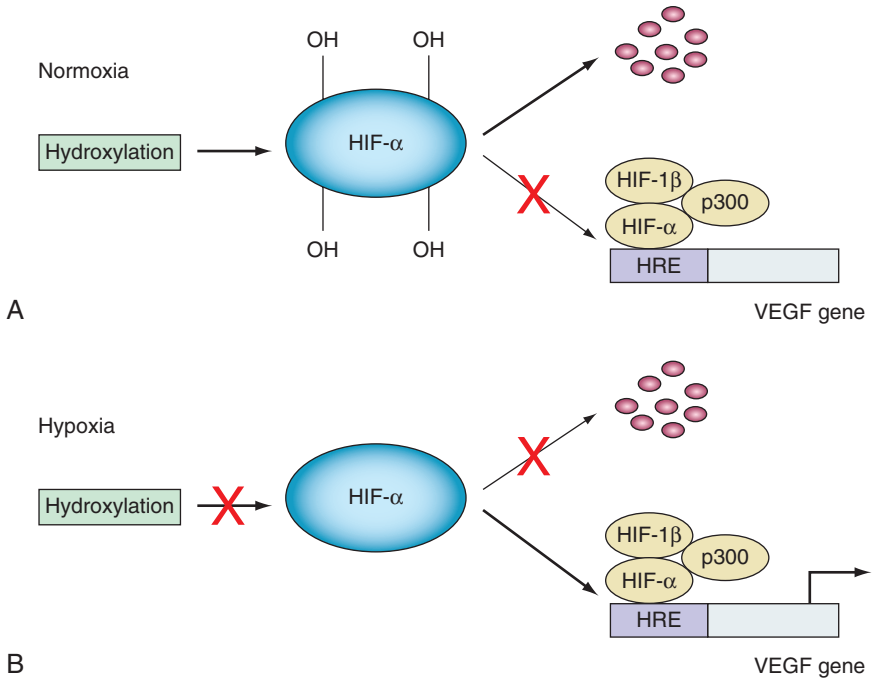

**Figure 25-2** Regulatory events in the hypoxia-hypoxia–inducible factor (HIF)–vascular endothelial growth factor (VEGF) cascade. Under a normoxic state, HIF-α is heavily hydroxylated, which leads to HIF degradation. Under a hypoxic state, HIF-α is dehydroxylated, translocates to the nucleus, and binds to HIF-1β. This results in binding of the HIF complex to hypoxia responsive elements (HRE) found in the VEGF gene and other angiogenic mediators.

and -2), epidermal (EGF), hepatocyte (HGF), keratinocyte (KGF), insulin-like (IGF-I), connective tissue (CTGF), platelet-derived (PDGF), and TGF-β, have been implicated in synovial angiogenesis. Many of these growth factors are bound to heparin and heparan sulfate proteoglycans in the synovial ECM, and they are mobilized by proteases during neovascularization.[1,14-16,109,110]

Pro-inflammatory cytokines may exert direct angiogenic activity or may act indirectly via VEGF-dependent pathways. Among these mediators, TNF, IL-1, IL-6, IL-15, IL-17, IL-18, oncostatin M, MIF, granulocyte colony-stimulating (G-CSF) and granulocyte-macrophage colony-stimulating factors (GM-CSF) have been implicated in synovial angiogenesis.[14,110,118-120]

Numerous chemokines and chemokine receptors described previously have been implicated in angiogenesis underlying RA. The angiogenic nature of most CXC chemokines has been associated with the ELR amino acid motif within their structure. The most relevant ELR-containing CXC chemokines that mediate angiogenesis include CXCL1, 5, 7, and 8.[13,16,64,121] In contrast, the ELR-lacking CXCL4, 9, and 10 inhibit angiogenesis.[8] CXCL12 is also angiogenic despite the fact that this chemokine lacks the ELR motif.[7] Among CC chemokines, CCL2 induces EC chemotaxis in vitro and angiogenesis in vivo. CCL23 has been implicated in the migration of vascular ECs and MMP production. $CX_3CL1$ is involved in both angiogenesis and atherosclerosis underlying inflammatory rheumatic diseases. Among chemokine receptors, CXCR2 may be the most relevant to ELR-containing angiogenic CXC chemokines, such as CXCL1, 5, and 8 on ECs. CCR2-CCL2 and CCR7-CCL21 interactions are also involved in synovial neovascularization.[8,116]

Several ECM components, CAMs, and proteases have been implicated in adhesive and angiogenic processes in RA. Type I collagen, fibronectin, laminin, vitronectin, tenascin, and proteoglycans mediate, whereas thrombospondin 1 (TSP-1) inhibits EC adhesion and neovascularization. As described previously, some growth factors bind to proteoglycans during angiogenesis. Among CAMs, most $\beta_1$ and $\beta_3$ integrins, E-selectin, the L-selectin ligand CD34, selectin-related glycoconjugates, including Lewis$^y$/H and MUC18, VCAM-1, PECAM-1, endoglin, and JAMs are expressed on the EC surface and promote angiogenesis. MMPs, ADAM, and ADAMTS proteases digest the ECM, release growth factors and other angiogenic mediators, and thus promote neovascularization in RA.[3,4,14,107,108,122,123]

Lewis$^y$/H, as well as fucosyl-transferase 1 (FUT1) that synthesizes Lewis$^y$/H have been implicated in angiogenesis, synovial fibroblast proliferation, and monocyte recruitment.[124-126] Lewis$^y$/H and its analog H-2g stimulate endothelial CAM expression and the release of angiogenic growth factors.[125] In the K/BxN serum transfer model, a mouse model for inflammatory arthritis, FUT1 gene–deficient mice were resistant to development of arthritis and also exhibited decreased angiogenesis and leucocyte ingress into inflamed joints.[127] Moreover, FUT1 is also responsible for the fucosylation of a number of human synovial RA antigens. For instance, RA synovial tissue ECs exhibit high expression of α.[1,2] linked fucosylated proteins compared with normal synovial tissue ECs. Depletion of these proteins in RA synovial fluid reduced the ability of these proteins to induce EC migration.[128] These findings suggest that FUT1 may be a novel therapeutic target in RA.

Further angiogenic factors relevant to RA include, without mentioning further details, serum amyloid A

(SAA), ET-1, members of the cyclooxygenase-2 (COX-2)-$PGE_2$ network, angiogenin, angiotropin, pleiotrophin, platelet-activating factor (PAF), substance P, erythropoietin, adenosine, histamine, prolactin, thrombin, sphingosine-1-phosphate (S1P), and many others.[1,14-16,109,115]

### Vasculogenesis in Arthritis

EPCs are hematopoietic stem cells that express, among other antigens, CD34, CD133, type 2 VEGF receptors, and CXCR4. During vasculogenesis, EPCs differentiate into mature ECs. Defective vasculogenesis due to impaired EPC numbers and functions has been described in RA. Effective control of inflammation with corticosteroids and TNF inhibitor agents may stimulate EPCs and thus may restore vasculogenesis. In addition, the induction of vasculogenesis may also suppress premature atherosclerosis in RA.[16,129,130]

## CELLULAR AND MOLECULAR REGULATION OF LEUKOCYTE RECRUITMENT AND ANGIOGENESIS

### Process of Leukocyte Extravasation in Inflammation

Adhesion of peripheral blood leukocytes to endothelium leads to the process of leukocyte transendothelial migration into inflammatory sites, such as the RA synovium.[2-4] High endothelial venules (HEV), primarily found in lymphoid organs, are also present at sites of lymphoid neogenesis in the synovial tissue.[3,131,132] Lymphocytes recirculate through HEVs during homing; thus inflammatory leukocyte recruitment may be considered as pathologic homing.[3,4,132]

During leukocyte adhesion and transendothelial migration, an early, weak adhesion termed "rolling" occurs first. This step involves selectins and their ligands and leads to leukocyte activation. Activation-dependent, firm adhesion involves mostly integrin-dependent interactions, primarily ICAM-1 and VCAM-1, as well as the secretion of numerous chemokines. Chemokines preferentially attract endothelium-bound leukocytes. Transendothelial migration may be the point of no return in inflammation.[2,6,133,134]

### Interactions among Chemokines, Adhesion Receptors, and Angiogenic Factors

The molecular mechanisms and signaling pathways of chemokine-induced CAM expression have been described. Treatment of cells with chemokines induces an atypical protein kinase C (PKC-ξ) through its interaction with PI3K. This leads to increased cell surface integrin expression via further signaling steps.[1] Another example for chemokine-CAM interactions is the regulation of $\beta_3$ integrin expression by CCL2 through the Ets-1 transcription factor. This pathway is involved in both inflammation and angiogenesis.[135] The CCL21-CCR7 interaction results in the stimulation of LFA-1- and ICAM-1–dependent adhesion.[136] Stimulation of CXCR1- and CXCR2-dependent pathways in arthritis models resulted in increased neutrophil adhesion to endothelium.[137] Thus various chemokines and chemokine receptors are involved in the process of leukocyte transendothelial migration.

As described previously, numerous ELR-containing CXC chemokines, CC chemokines, $CX_3CL1$ (fractalkine), and their receptors have been implicated in angiogenesis underlying RA.[8,13,15,121] Much less evidence has become available regarding the role of CC chemokines in angiogenesis. CCL2-induced angiogenesis may occur via $\beta_3$ integrins.[135] CCL23 has been implicated in the migration of vascular ECs.[48] Finally, $CX_3CL1$ (fractalkine) is involved in both angiogenesis and atherosclerosis underlying inflammatory rheumatic diseases.[8,37,38]

Both CAMs and their ECM ligands may mediate adhesive interactions during inflammatory neovascularization.[4,15,138] As discussed previously, most ECM components promote angiogenesis.[14,138] Vasculogenesis is stimulated by the laminin matrix Matrigel (Corning Life Sciences, Tewksbury, Mass.).[139] Among endothelial CAMs, soluble E-selectin; soluble P-selectin; the L-selectin ligand CD34; soluble VCAM-1; some endothelial $\beta_1$, $\beta_3$, and $\beta_5$ integrins; PECAM-1; endoglin; and some cadherins have been implicated in angiogenesis.[14,15,140-143] The $\alpha_V\beta_3$ integrin, as well as the *ITGAV* gene, play a critical role in angiogenesis. This integrin has become a major target for specific therapy.[135,142-144] Other angiogenic factors, such as chemokines, may act via integrin-dependent pathways.[135] Focal adhesion kinases (FAK) are involved in the $\alpha_V\beta_3$ integrin signaling that underlies synovial inflammation and angiogenesis.[145] Among glycoconjugates with adhesive properties, blood group antigens $Lewis^y$ and H promote neovascularization.[124] JAMs have also been implicated in the adhesive processes underlying RA, as well as in synovial angiogenesis.[56,12] Vasculogenesis also involves many integrins, including $\alpha_V\beta_3$, as well as E-selectin.[1,146-149]

## TARGETING CELL ADHESION, CHEMOKINES, ANGIOGENESIS, AND VASCULOGENESIS IN INFLAMMATORY RHEUMATIC DISEASE

Leukocyte recruitment inhibition may be a result of nonspecific anti-inflammatory therapeutic strategies. Numerous traditional and biologic disease-modifying drugs (DMARDs) and immunosuppressive agents may, in addition to other effects, suppress leukocyte recruitment, chemokine production and angiogenesis. Inhibition of cell adhesion and migration, angiogenesis, chemokines, and chemokine receptors with the use of specific antibodies or purified ligands has provided an important perspective on the molecular pathogenesis of RA. In addition, some of these strategies may be included in the therapy of arthritis.[3,4,8,15,16,150-153]

### Inhibition of Cell Adhesion Receptors

Certainly, corticosteroids and other immunosuppressive drugs may have modulatory effects on CAM expression and inflammatory cell adhesion[3,4,154]; however, these nonspecific therapies will not be further discussed.

Regarding specific anti-CAM targeting in humans, first an antihuman ICAM-1 antibody (enlimomab) was used to treat refractory RA. Repeated administration of this antibody resulted in diminished efficacy and frequent adverse events, therefore further development of enlimomab in RA was terminated.[3] Two anti-integrin strategies, (1) the

anti-LFA-1 antibody efalizumab, and (2) the LFA-3–Ig fusion protein alefacept, have been registered for the treatment of psoriasis. Alefacept also yielded a moderate effect in psoriatic arthritis.[155] Efalizumab has recently been withdrawn from the market due to severe side effects. Various other anti-integrin and anti-CD44 antibodies have been tried in animal models of arthritis, but not in human disease.[3,4,53] RGD and other peptides that block CAMs have also been tried in arthritis models.[156] The high number of CAMs and the redundancy of the adhesion network and multiple regulatory pathways may account for the notion that targeting of one CAM may be technically feasible but often yields disappointing results in human trials.

## Chemokine and Chemokine Receptor Targeting

Chemokines and chemokine receptors may be targeted by both indirect and nonspecific and direct, chemokine-specific approaches. Again, only specific targeting will be discussed in more detail; however, some nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, and traditional and biologic DMARDs may, in addition to their other anti-inflammatory effects, inhibit chemokines and chemokine receptors.[10,61,67,157-159]

Some other synthetic compounds, as well as natural products, may also influence chemokine secretion. For example, antioxidants such as *N*-acetyl-L-cysteine and 2-oxothiazolidine-4-carboxylate, the bioflavonoid quercetin, and the lipid-lowering simvastatin inhibited the expression of CXCL8 and CCL2 by activated, cultured human synovial fibroblasts.[160-162] Epigallocatechin-3-gallate (EGCG), a compound derived from green tea, as well as green tea extracts, suppressed the production of multiple chemokines, including CXCL1, CXCL5, CCL2, and CCL5, by cultured RA synovial fibroblasts, bone cells, and in a rat model of arthritis.[163-165] Activation of peroxisome proliferator-activated receptor γ (PPARγ) suppresses CCL2 expression in monocytes[166]; thus PPARγ agonists, such as glitazones, may inhibit chemokine production. Some traditional Oriental medicines, such as triptolide, lingzhi, curcumin, tongbiling, honokiol, cool-cool, and others exert antiarthritic effects, which may, in part, be explained by chemokine and chemokine receptor inhibition.[158,167-173]

With respect to specific molecular targeting, neutralizing antibodies to CXCL1, 5, 8, and 16; CCL2, 3, 5, and 24, and $CX_3CL1$ blocked arthritis both therapeutically and preventatively in various RA animal models.[85,174-180] Again, because of the complexity of and several regulatory loops in the chemokine network, most of these approaches failed in human RA. There has only been a very limited number of human antichemokine trials. An anti-CCL2 antibody, ABN912, was evaluated in a randomized, placebo-controlled study. A total of 33 patients received the active compound, whereas 12 received a placebo. Serial arthroscopic biopsies were performed. ABN912 treatment was well tolerated, but there was no detectable clinical benefit or significant changes in synovial biomarkers.[181] This trial was completed in 2006 and not followed by others, suggesting that targeting of a single chemokine may not be effective in arthritis.

Targeting of chemokine receptors that recognize multiple ligands may be more feasible. Some CXCR antagonists have been used in animal models but have not been tested in human RA.[182-189] To our knowledge, no clinical trial results obtained with any CXCR antagonists in arthritis have been published.

CCR1, 2, and 5 bind multiple CC chemokine ligands that have been implicated in the pathogenesis of RA,[10,11,61,87,157] including CCL3, 5, 7, 8, 14, 15, and 16. Therefore numerous synthetic or biologic CCR1, 2, and 5 antagonists have been developed in recent years.[157,190-198] CCR1 is a receptor for CCL3, 5, 7, 14, 15, and 16. Among CCR1 antagonists, in early pre-clinical studies, J-113863 diminished synovitis and joint destruction in murine collagen-induced arthritis (CIA).[199] Met-RANTES, a dual CCR1/CCR5 antagonist, inhibited both murine CIA and rat adjuvant-induced arthritis (AIA).[200,201] This was followed by the development and introduction of two oral CCR1 antagonists, CP-481,715, and MLN3897 to human RA trials.[157,195] In a phase I trial, CP-481,715 was administered to 78 healthy individuals in escalating doses as high as 3000 mg. This drug was well tolerated.[176] CP-481,715 has also been evaluated in a 2-week phase Ib, proof-of-concept study in RA patients with a dose of 300 mg every 8 hours. A total of 16 RA patients were randomly assigned 3 : 1 with active placebo treatment for 14 days. Treatment decreased the number of total and intimal macrophages, as well as $CCR1^+$ cells in the synovium. Approximately one-third of the patients also fulfilled the American College of Rheumatology response criteria (ACR20) for clinical improvement.[202] In a subsequent phase IIa study, RA patients with active disease despite methotrexate treatment received either 10 mg of MLN3897 or a placebo orally once daily with concomitant methotrexate therapy. Although MLN3897 was well-tolerated, no difference in ACR20 was found between the active and placebo group. Interestingly, MLN3897 was associated with a relatively high degree (≥90%) of CCR1 occupancy throughout the trial as determined by CCL3 internalization assays.[191]

CCR2 recognizes CCL2, CCL7, and CCL16. Some CCR2 inhibitors have also been tried in animal studies and then clinical trials.[203] In a phase IIa clinical trial with a CCR2 blocking antibody MLN1202, 32 patients with active RA received three infusions of either placebo or anti-CCR2 antibody at 0.5 mg/kg or 1.5 mg/kg during a period of 6 weeks. The antibody reduced the levels of free CCR2 on $CD14^+$ monocytes; however, no clinical benefit could be demonstrated.[190]

CCR5 binds CCL3, 5, 8, and 14. As discussed previously, in earlier studies, Met-RANTES and other small-molecule antagonists showed some efficacy in pre-clinical arthritis studies.[200,201,204] A small-molecule CCR5 antagonist, AZD5672 has been studied in pre-clinical, phase I and IIb studies. In the phase IIb trial, 371 patients with active RA received various doses of oral AZD5672 once daily, a placebo, or open-label etanercept, 50 mg subcutaneously (SC), once weekly. There was no significant difference in the number of patients receiving the active compound or placebo. Furthermore, etanercept was more effective than AZD5672 or placebo.[196] A phase Ib trial was conducted with SCH351125, a small-molecule oral CCR5 inhibitor. Among 32 patients with active RA, 20 received the active compound and 12 received placebo. No synovial, magnetic resonance imaging, or clinical efficacy could be proved.[197]

Another CCR5 inhibitor, maraviroc, has been examined in a phase II trial in RA.[205] Thus CCR2 and CCR5 blockade yielded disappointing results in RA, and results for CCR1 blockade have been variable.

## Angiogenesis Targeting: Use of Angiostatic Compounds

Angiogenesis can be inhibited by either blocking the action of angiogenic mediators or by using angiostatic compounds[14,112,115,152,153] (see Table 25-3). Currently used antirheumatic agents, such as rofecoxib, dexamethasone, chloroquine, sulfasalazine, methotrexate, azathioprine, cyclophosphamide, leflunomide, thalidomide, tacrolimus, minocycline, and anti-TNF biologics, apart from their other important anti-inflammatory effects, nonspecifically suppress angiogenesis, including VEGF and/or Ang1/Tie2.[14,152,153] For example, TNF blockade by infliximab reduced VEGF expression and vascularity within the RA synovium. Infliximab also reduced synovial Ang1 and Tie2 expression. Certolizumab pegol inhibits TNF-dependent angiogenesis. The anti–IL-6 receptor antibody tocilizumab also decreased serum levels of VEGF in RA.[14,115,118,206] IL-17 has been implicated in inflammatory angiogenesis, therefore, anti–IL-17 blockade may also be feasible in this respect.[120] RGD and other peptides that inhibit angiogenesis have also been tried in animal models of arthritis.[156]

VEGF inhibitors have been used in both arthritis trials and cancer studies. These inhibitors may include antibodies to VEGF or VEGF receptors (VEGFR), soluble VEGFR constructs, small-molecule VEGF and VEGFR inhibitors, or inhibitors of VEGF and VEGFR signaling. The VEGF tyrosine kinase inhibitor vatalanib (PTK787) and an anti-VEGFR1 antibody exerted significant angiostatic and antiarthritic effects in animal models of arthritis. A soluble VEGFR1 chimeric protein inhibited synovial endothelial proliferation.[1,14,112,115,152,153]

The involvement of PPARs in hypoxia-induced VEGF production is discussed previously. PPARγ ligands rosiglitazone and pioglitazone have been found to inhibit VEGF-induced angiogenesis.[14] HIFs may also be targeted in arthritis. For example, YC-1, a superoxide-sensitive stimulator of soluble guanylyl cyclase and an HIF-1 inhibitor, may potentially be used to suppress inflammatory angiogenesis.[114,152] As far as the Ang1/Tie2 system is concerned, a soluble Tie2 receptor transcript, delivered via an adenoviral vector to mice, attenuated the incidence and severity of CIA.[14,152] An Ang2-targeting peptide was genetically fused to the anti-TNF antibody adalimumab. This novel bispecific antibody enhanced anti-TNF efficacy.[156]

Antibiotic derivatives, including minocycline, fumagillin analogues, deoxyspergualin, roxithromycin, and clarithromycin, also inhibit the release of VEGF and other angiogenic mediators, and thus inhibit neovascularization. Synthetic fumagillin derivativesTNP-470 and PPI-2458 inhibit VEGF and VEGF-dependent angiogenesis. These have been used in human RA trials, in which minocycline, roxithromycin, and clarithromycin were found to exert moderate but significant clinical effects.[14,109,152,153]

Among other inhibitors of angiogenic mediators, ET-1 antagonists currently used in the treatment of pulmonary hypertension may also exert antiangiogenic effects.[207] S1P and also angiogenic and S1P inhibitors, such as fingolimod (FTY720), are in clinical trials for various autoimmune diseases. FTY720 also acts as an inhibitor of FAKs as described previously.[14,123,152,153] Peptides have been isolated from libraries of phages that preferentially home to inflamed joints of AIA rats. Some of these peptides that bind to synovial endothelial cells were found to inhibit arthritis in addition to VEGF signaling and angiogenesis.[156]

In recent years, an emerging number of compounds in traditional Chinese and Korean medicine have been implicated in angiogenesis research. A number of these compounds may have angiostatic effects in arthritis,[14] including scopolin, a coumarin derivative found in *Erycibe obtusifolia* Benth; celastrol, an active ingredient of *Tripterygium wilfordii*, also known as "Thunder God Vine"; and fisetin, the active ingredient of *Rhus verniciflua* Stokes.

## Restoration of Impaired Vasculogenesis

Corticosteroids and TNF inhibitor agents may stimulate EPCs and thus restore vasculogenesis in RA. The CXCL12 (SDF-1) inhibitor bicyclam (AMD3100) has been found to mobilize EPCs in mice. Although the number of EPCs correlate with the improvement of DAS28 in RA, the suppression of systemic inflammation and disease activity by any means would improve vasculogenesis.[16,130]

# CONCLUSION

Leukocyte-endothelial adhesion, CAMs, chemokines, chemokine receptors, angiogenesis, and vasculogenesis in leukocyte recruitment underly many inflammatory diseases. The presence of various CAM pairs and interacting chemokines may account for the diversity and specificity of leukocyte recruitment. A number of soluble and cell-bound factors may stimulate or inhibit angiogenesis. The outcome of inflammatory and other "angiogenic" diseases, such as various forms of arthritis, depends on the imbalance between angiogenic and angiostatic mediators. Some CAMs and chemokines, as well as growth factors, proteases, antibiotics, and other agents are also involved in neovascularization. Impaired EPC function and vasculogenesis have been associated with active arthritis. Several attempts have been made to therapeutically interfere with the cellular and molecular mechanisms described in this chapter. Specific targeting of leukocyte adhesion, CAMs, chemokines, chemokine receptors and/or angiogenesis, as well as the restoration of defective vasculogenesis, have been studied in animal systems; however, more human trials are necessary.

CHAPTER 26

# Cytokines

Iain B. McInnes

**KEY POINTS**

- **Cytokines are peptides that have a fundamental role in communication within the immune system and in allowing the immune system and host tissue cells to exchange information.**
- **Cytokines act via binding to a receptor that in turn sends a signal to the recipient cell, leading to a change in function or phenotype. Such signal cascades are complex and integrate a variety of environmental factors.**
- **Cytokines exist in broad families that are structurally related but exhibit diverse function (e.g., the TNF/TNF receptor superfamily, interleukin [IL]-1 superfamily, and IL-6 superfamily).**
- **Cytokine targeting has proven effective in many rheumatic diseases, particularly therapeutics that inhibit TNF or IL-6. Many more cytokines are currently under investigation as therapeutic targets or as therapeutic agents.**

Immune function depends on the biologic activities of numerous small glycoprotein messengers termed *cytokines*. Originally discovered and defined on the basis of their functional activities, cytokines are now designated primarily by structure. Typically, cytokines exhibit broad functional activities that mediate not only effector and regulatory immune function but also have wider effects across a range of tissues and biologic systems. As such, cytokines play a role not only in host defense but also in a variety of normal physiologic and metabolic processes. By this means they integrate de facto host defense and host metabolic function. The Human Genome Project has assisted with the discovery of numerous cytokines, posing considerable challenges in resolving their respective and synergistic functions in complex tissues in health and disease. However, such understanding is essential with the increasing application of cytokine-targeted therapies in the clinic. This chapter reviews general features of cytokine biology and the cellular and molecular networks within which cytokines operate; the focus is on the effector functions of cytokines that are important in chronic inflammation and in rheumatic diseases.

## CLASSIFICATION OF CYTOKINES

In the absence of a unified classification system, cytokines are variously identified by numeric order of discovery (currently interleukin [IL]-1 through IL-38); by a given functional activity (e.g., tumor necrosis factor [TNF] and granulocyte colony-stimulating factor); by kinetic or functional role in inflammatory responses (e.g., early or late, innate or adaptive, and pro-inflammatory or anti-inflammatory); by primary cell of origin (e.g., monokine = monocyte derivation and lymphokine = lymphocyte derivation); and, more recently, by structural homologies shared with related molecules. Superfamilies of cytokines share sequence similarity and exhibit homology and some promiscuity in their reciprocal receptor systems (Figure 26-1). They do not necessarily exhibit functional similarity. Cytokine superfamilies also contain important regulatory cell membrane receptor-ligand pairs, reflecting evolutionary pressures that use common structural motifs in diverse immune functions in higher mammals. The TNF/TNF receptor superfamily[1] contains immunoregulatory cytokines including TNF, lymphotoxins, and cellular ligands such as CD40L, which mediates B cell and T cell activation, and FasL (CD95), which promotes apoptosis. Similarly, the IL-1/IL-1 receptor superfamily[2] contains cytokines including IL-1β, IL-1α, IL-18, IL-33, and IL-36 (α, β, γ), receptor antagonists including IL-1RA, IL-36 receptor antagonist, IL-38, and an anti-inflammatory cytokine, namely IL-37, which mediate physiologic and host-defense function, but this family also includes the Toll-like receptors (TLRs), a series of mammalian pattern-recognition molecules with a crucial role in recognition of microbial species early in innate responses.

## ASSESSING CYTOKINE FUNCTION IN VITRO AND IN VIVO

Although they were originally identified by bioactivity and quantified by bioassay, most cytokines are now identified via homologous receptor binding or sequence homology in gene databases. They are quantified in biologic solutions by enzyme-linked immunosorbent assay, multiplex technology, or meso platform techniques, with the latter allowing many cytokines (25 to 360) to be measured in single, small sample volumes (~20 μL). Cytokines are also assessed in experimental systems at the messenger RNA (mRNA) level, often using quantitative polymerase chain reaction (PCR) or Taqman low-density array (TLDA)-based approaches; the latter allows many cytokines to be identified in small samples simultaneously. Post-transcriptional regulation of cytokines is common, however, suggesting cautious interpretation of mRNA data alone. Function is thereafter assessed by

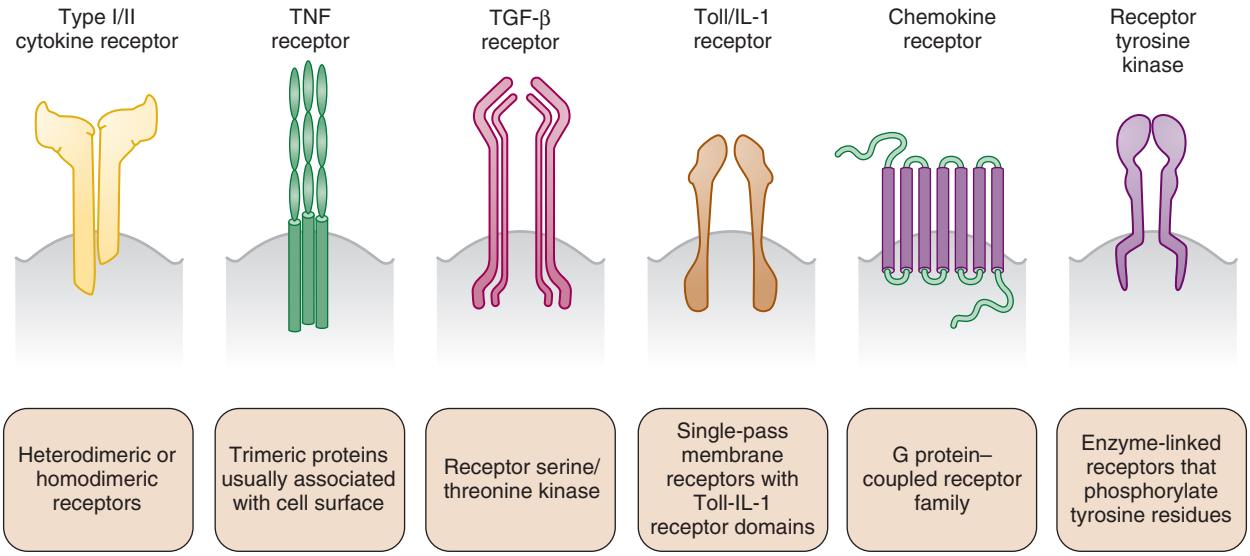

**Figure 26-1** Cytokine receptors. Cytokines, chemokines, and growth factors bind to many different types of surface receptors in the cell membrane. The figure shows several distinct families and representative ligands that are critical. Each receptor type is associated with distinct signaling mechanisms that orchestrate and integrate the cellular response after ligand binding. IL-1, Interleukin-1; TGF-β, transforming growth factor-β; TNF, tumor necrosis factor.

identification of the cellular source of cytokine, determination of native stimuli, characterization of receptor distribution, and determination of function in target cells. Experimental in vivo models use the addition of neutralizing cytokine-specific antibodies or soluble receptors (often as fragment crystallizable fusion or pegylated proteins to enhance half-life and modulate functional interaction with leukocytes) to modulate cytokine function. Genetically modified knockout and knockin mice (cytokine or receptor modified by embryonic stem cell technology) or transgenic mice (tissue/cell lineage–specific overexpression) have proven particularly useful. Conditional gene-targeting approaches (e.g., using the Cre system) facilitate circumvention of embryonic lethal deficiencies or allow kinetic evaluation of the relative contribution of a cytokine throughout a response. Moreover, recent multiphoton microscopic techniques have allowed the additional evaluation of cytokine contributions in three-dimensional tissue orientation and in real time in vivo. Cytokine function is normally assessed in vitro in primary or transformed cell lines stimulated in the presence or absence of recombinant cytokine or specific anti-cytokine antibody or soluble receptor. Gene knock-down approaches with use of small interfering (si)RNA or antisense oligonucleotides are also increasingly employed. Recently CRISPR (clustered regularly interspaced short palindromic repeats) and TALEN (transcription activator-like effector nucleases)-based technologies have facilitated highly specific cytokine and cytokine receptor knock-down cell work.

This general approach has been crucial in rheumatic disease research. Studies in which cytokine addition and neutralization occur in synovial tissue explants or disaggregated cell populations, chondrocyte explants, bone culture models, skin, and renal tissue explants and cell lines have been informative. Ex vivo methodologies now include intra-cellular fluorescence activated cell sorter methods, confocal and laser scanning microscopy, and quantitative histologic evaluation using automated image analysis. Such modalities, particularly when used in human therapeutic cytokine neutralization studies in which inflammatory tissues are obtained throughout therapeutic interventions, advance the understanding of basic and pathogenetic cytokine function. Analysis of synovial biopsy specimens obtained before and after infliximab, adalimumab, abatacept, rituximab, tocilizumab, IL-1RA, IL-10, and interferon (IFN)-β administration in persons with rheumatoid arthritis (RA) provides the strongest evidence for the success of this approach.[3,4]

## CYTOKINE RECEPTORS

Cytokine receptors exist in structurally related superfamilies and comprise high-affinity molecular signaling complexes that assist in cytokine-mediated communication (see Figure 26-1). Such complexes often include heterodimeric or heterotrimeric structures that use unique, cytokine-specific recognition receptors together with common receptor chains shared across a cytokine superfamily. Examples include the use of the common γ chain receptor by IL-2, IL-4, IL-7, IL-9, IL-15, IL-21, and glycoprotein (gp)130 by members of the IL-6 family.[5,6] Alternatively, distinct receptors may use shared signaling domains. Homologous death domains are found in many TNF-receptor family members. Similarly, the IL-1 signaling domain is common to not only IL-1R but also other IL-1R superfamily members, including IL-18R, IL-33R, and the TLRs.[2] It has been recognized more recently that unrelated cytokine receptor systems exhibit close cross-communication on the cell membrane, allowing a cell to integrate a variety of external stimuli to optimize signaling pathways and the cellular response in real time in a changing environment. Although best elucidated in the epidermal growth factor receptor system, this mechanism also has been identified for members of the common γ chain signaling family. Signaling pathways that subserve these responses are discussed in detail elsewhere (see Chapter 27).

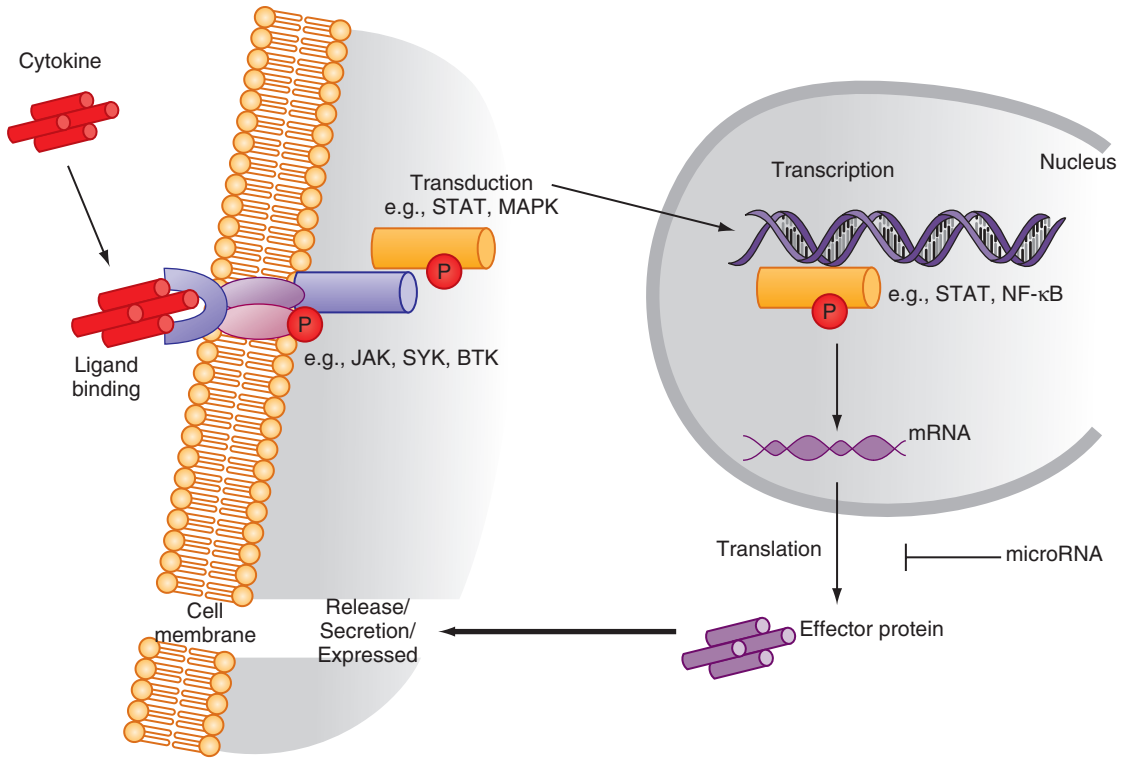

**Figure 26-2** Cytokine signaling and regulation. After ligand binding, cytokine receptors activate a series of signaling molecules that are associated with the cytoplasmic portion of the receptor or the plasma membrane. In this figure, Janus kinase (JAK) or spleen tyrosine kinase (SYK) is activated, which in turn phosphorylates additional cytoplasmic molecules (signal transducer and activator of transcription [STAT]; mitogen-activated protein kinase [MAPK]) that then can migrate to the nucleus and either directly or through additional intermediaries activate gene transcription. Messenger RNA (mRNA) levels can also be regulated after transcription by microRNAs. Ultimately, the translated proteins can be processed and released by the cell into the microenvironment or presented on the plasma membrane to other cells. BTK, Bruton's tyrosine kinase; NF-κB, nuclear factor-κB.

Cytokine receptors can operate via several mechanisms. Membrane receptors, with intra-cellular signaling domains intact, can transmit signals to the target cell nucleus after soluble cytokine binding and promote effector function (Figure 26-2). Membrane receptors may bind cell membrane cytokines assisting cross-talk between adjacent cells. Membrane-bound and soluble cytokines may promote distinct receptor function. Useful exemplars exist relevant to the rheumatic diseases. Thus TNF binds TNF-RI and TNF-RII with similar affinity, but it has a slower rate of dissociation from TNF-RI. Soluble TNF may dissociate rapidly from TNF-RII to bind TNF-RI, promoting preferential signaling by the latter (ligand passing).[1] In contrast, during cell-cell contact, stable TNF/TNF-RI and TNF/TNF-RII complexes form, allowing for differential signaling contribution by TNF-RI and TNF-RII.

Cytokine receptor/cytokine complexes also may operate in trans, whereby component parts of the ligand-receptor complex are derived from adjacent cells. IL-15/IL-15Rα complexed on one cell may bind IL-15Rβ/γ on another.[7] Receptors also exist in soluble form, derived either from alternative mRNA processing to generate receptor-lacking transmembrane or intra-cellular domains or from enzymatic cleavage of receptor from the cell surface (e.g., soluble TNF-R [sTNF-R] and soluble IL-1R1 [sIL-1R1]). Soluble receptors may act to antagonize cytokine function, thus regulating responses. Soluble receptors also may pre-form complexes with cytokine to promote subsequent ligand-receptor assembly on the target cell membrane and enhance function. Soluble receptors can deliver cytokine to the cell membrane via ligand passing. IL-6 provides a particularly important example given its core role in a range of rheumatic disorders. IL-6 binds to a heterodimeric receptor (IL-6R and gp130) and provokes cell activation thereby via conventional signal pathways that involve signal transducer and activator of transcription (STAT)-3. Thus IL-6 may activate a cell expressing the combination of IL-6R and gp130 by conventional (cis) signaling. In addition, however, circulating soluble IL-6R may form functional gp130/IL-6R effector complexes on any cell expressing membrane gp130 and by this means confer on circulating IL-6 the ability to exert broad functional effects (trans signaling). Finally, it is now recognized that some cytokines with the capacity to be retained in the membrane may themselves function as signaling molecules (reverse signaling).

## REGULATION OF CYTOKINE EXPRESSION

Cytokines are synthesized in the Golgi apparatus and may traffic through the endoplasmic reticulum to be released as soluble mediators, or they may remain membrane bound, or they may be processed into cytosolic forms that can traffic intra-cellularly, even returning to the nucleus, where they can act as transcriptional regulators. Cytokines mediate autocrine function either through release or membrane expression and immediate receptor ligation on the source

cell or intra-cellularly within the source cell. Alternatively, cytokines operate in a paracrine manner, allowing cellular communication beyond that assisted by local cell-cell contact. The distance and kinetics for effective function may be limited,[8] however, by numerous factors, including physicochemical considerations of the peptide structure itself, extra-cellular matrix binding (e.g., to heparan sulfate), enzymatic degradation (e.g., serine protease degradation of IL-18), or the presence of soluble receptors (e.g., TNF/soluble TNF-RI and TNF-RII and IL-2/soluble IL-2Rα) or novel cytokine-binding proteins (e.g., IL-18/IL-18 binding protein) in the inflammatory milieu.

Numerous factors promote cytokine expression in vivo (Figure 26-3), including cell-cell contact, immune complexes/autoantibodies, local complement activation, microbial species and their soluble products (particularly via TLRs and nucleotide oligomerization domain [NOD]-like receptors [NLRs]), reactive oxygen and nitrogen intermediates, trauma, shear stress, ischemia, radiation, ultraviolet light, extra-cellular matrix components, DNA (mammalian or microbial), heat shock proteins, electrolytes (e.g., $K^+$ via $P_2X7$ receptors), and cytokines themselves operating in autocrine loops. Commonly used in vitro stimuli include many of these factors and chemical entities including phorbol esters, calcium ionophores, lectins (e.g., phytohemagglutinin), and receptor-specific antibodies such as anti-CD3 and anti-CD28 for T cell activation or anti-immunoglobulin and anti-CD40 for B cells.

Cytokine regulation within the cell can be usefully considered at several levels (see Figure 26-2). Transcriptional regulation depends on the recruitment of discrete transcription factors to the cytokine promoter region. Transcription factor binding allows for numerous signal pathways to regulate cytokine expression across a range of stimuli. Several transcription factors (e.g., nuclear factor-κB [NF-κB], activator protein [AP]-1, and nuclear factor of activated T cell) are crucial in cytokine production. Inhibition of NF-κB activity using either chemical inhibitors or adenoviral delivery of regulatory peptides leads to amelioration of inflammatory synovitis in vivo and in vitro.[9] Sequence polymorphism within cytokine promoters offers potential for differential cytokine expression between individuals that could confer selective advantage against infection but could also increase susceptibility to, or progression of, autoimmunity. This potential is best exemplified in the TNF and IL-1 promoters.[10,11] Single nucleotide polymorphisms in the TNF promoter region (e.g., −308) are associated with altered TNF release on leukocyte stimulation in vitro. Similarly, homozygotes for the A2 allele at +3954 in the IL-1β gene produce more IL-1β with lipopolysaccharide stimulation. Polymorphisms also exist in the *IL-1RA* gene, rendering the functional significance of individual single nucleotide polymorphisms on IL-1 protein release difficult to interpret. In general, the net effect of haplotypes may be more important at the functional level or only play a role in the context of networks where multiple minor polymorphisms can synergize, particularly when their relevance to disease entities is considered.

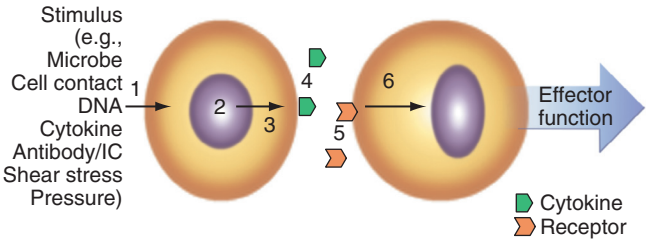

**Figure 26-3** Overview of cytokine regulatory function. Numerous and diverse stimuli *(1)* promote cytokine expression arising either from novel gene expression *(2)* or from activation of pre-formed cytokine *(3)*. Cytokine proteins are thereafter expressed in the cytosol, on the cell membrane, or in soluble form in the extra-cellular environment *(4)*. Cytokines bind to reciprocal receptors that reside either on the membrane of a target cell or in the soluble phase *(5)*. Membrane receptors, on cytokine ligation, signal to the recipient cell nucleus *(6)* and drive novel gene expression to promote effector function. Each phase of cytokine function offers rich therapeutic potential. IC, Immune complexes.

Post-transcriptional regulation is important in determining longevity of cytokine expression. This regulation may operate by promoting translational initiation, mRNA stability, and polyadenylation. AU-rich elements (AREs) within the 52 or 32 untranslated regions (UTRs) of cytokine mRNA are crucial for stability; 32 UTR AREs downregulate TNF expression such that transgenic knockin mice that lack TNF AREs develop spontaneous inflammatory arthritis and bowel disease.[12] Regulatory proteins bind AREs to mediate such effects. HuR and AUF1 exert opposing effects, stabilizing and destabilizing ARE-containing transcripts.[13] TIA-1 and TIAR have been identified as RNA recognition motif family members[14] that function as translational silencers. Macrophages from TIA-1–deficient macrophages produce excess TNF, whereas TIA-1–deficient lymphocytes exhibit normal TNF release, suggesting distinctions in mRNA regulation in discrete cell types.[15] Alternatively, cytokines may generate stable mRNA a priori to assist with subsequent rapid response in tissues. The IL-15 mRNA 52 UTR contains 12 AUG triplets that significantly reduce the efficiency of IL-15 translation. Deletion of this sequence permits IL-15 secretion. IL-15 mRNA can produce a 48 amino acid signal peptide that allows IL-15 release and a shorter 21 amino acid signal peptide that targets intracellular distribution. IL-15 forms thus generated exhibit discrete functions.[16]

Post-translational regulation also modulates cytokine expression via several mechanisms. Patterns of glycosylation are important for cytokine function and may regulate intracellular trafficking.[16] Modified leader sequences can alter intra-cellular trafficking of cytokines. Some cytokines are translated without functional leader sequences. Their secretion depends on nonconventional secretory pathways that are poorly understood. IL-1β employs, among other pathways, a purine receptor–dependent pathway ($P_2X_7$) for cellular release.[17] Enzymatic activation of cytokines is common, whereby nonfunctional promolecules are cleaved to generate functional subunits. Examples include the cleavage by caspase 1 of pro-IL-1β to generate active IL-1β and, similarly, of pro-IL-18 to generate an active 18 kDa species.[18] This organized process occurs both sequentially (in time) and by orientation within the cell (in space). IL-1 processing occurs in a protein complex within the cytosol termed the *inflammasome*. The latter has attracted considerable interest as a therapeutic target in conditions such as

crystal-induced arthritis and in diseases that arise from mutations in certain inflammasome genes (e.g., cryopyrin; see Chapters 27, 94, 96, and 97).

Alternative processing pathways for cytokines include the serine proteases, proteinase 3 and elastase, and adamalysin family members. Enzyme cleavage pathways operate within and outside cells, providing for extra-cellular cytokine activation. Similarly, cell membrane enzymes serve to cleave membrane-expressed cytokine. Members of the adamalysin family regulate TNF release; TNF-converting enzyme cleaves and mediates the release of TNF and its receptors.[19] Extensive molecular machinery exists to regulate tightly not only the production and stability of cytokine mRNA but also its translation and cellular expression and distribution. At each level, opportunities exist for intervention and therapeutic cytokine modulation.

## EFFECTOR FUNCTION OF CYTOKINES

Cytokines possess pleiotropic and potent effector function in acute and chronic inflammatory responses. The identity, receptor specificity, and key effects of cytokines understood to have particular importance in the pathogenesis of human autoimmunity and chronic inflammation are summarized in Tables 26-1 through 26-8.

### Cytokines in Acute Inflammation

Cytokines operate at every stage in the crucial early events that promote acute inflammation. Cells that make up the innate immune response, including neutrophils, natural killer (NK) cells, macrophages, mast cells, and eosinophils, all produce and respond to cytokines generated within seconds of tissue insult. Cytokines prime leukocytes for response to microbial and chemical stimuli, upregulate adhesion molecule expression on migrating leukocytes and endothelial cells, and amplify the release of reactive oxygen intermediates, nitric oxide, vasoactive amines, and neuropeptides, as well as the activation of kinins and arachidonic acid derivatives, prostaglandins, and leukotrienes, which regulate cytokine release. Similarly, cytokines regulate the expression of complement processing and membrane defense molecules, scavenger receptors, NLRs, and TLRs. Cytokines, particularly IL-1, TNF, and IL-6, are crucial in driving the acute-phase response. Some moieties are designated "alarmins" on the basis of their very rapid induction or prior expression and critical early role in initiating inflammation (e.g., IL-33 and high mobility group box 1 [HMGB1]). Tables 26-1 through 26-8 provide descriptions of the function of cytokines expressed within the acute inflammatory response.

**TABLE 26-1** Interkeukin-1 Superfamily Cytokines with Roles in Rheumatic Disease

| Cytokine | Size (kDa) | Receptors | Major Cell Sources | Key Functions |
|---|---|---|---|---|
| IL-1β | 35 (pro)<br>17 (active) | IL-1RI<br>IL-1RAcP<br>IL-1RII (decoy) | Monocytes; B cells; fibroblasts; chondrocytes; keratinocytes | Fibroblast cytokine, chemokine, MMP, iNOS, PG release ↑<br>Monocyte cytokine, ROI, PG ↑<br>Osteoclast activation<br>Chondrocyte GAG synthesis ↓; iNOS, MMP, and aggrecanase ↑<br>Endothelial adhesion-molecule expression |
| IL-1α | 35 (pro)†<br>17 (active) | IL-1RI<br>IL-1RAcP<br>IL-1RII (decoy) | Monocytes; B cells; PMNs; epithelial cells; keratinocytes | Similar to IL-1β<br>Autocrine growth factor (e.g., keratinocytes) |
| IL-1Ra | 22 | IL-1RI<br>IL-1RAcP<br>IL-1RII | Monocytes | Antagonize effects of IL-1β and IL-1α |
| IL-18 | 23 (pro)<br>18 (active) | IL-18R<br>IL-18Rβα | Monocytes; PMNs; dendritic cells; platelets; endothelial cells | T cell effector polarization (Th1 with IL-12/Th2 with IL-4)<br>Chondrocyte GAG synthesis ↓; iNOS expression<br>NK activation; cytokine release; cytotoxicity<br>Monocyte cytokine release; adhesion molecule expression<br>PMN activation; cytokine release; migration<br>Endothelial cells—proangiogenic |
| IL-36 (αβγ) | 35 | IL-1Rrp2<br>IL-1RAcP | Macrophages, DC, lymphocytes, epithelial cells (skin, bronchial), FLS | Innate immune cell activation, cytokine production<br>Keratinocyte proliferation |
| IL-37 | 35 | IL-18Rα | Ill-defined | General anti-inflammatory function: transgenic mice protected from colitis, ischemia reperfusion injury |
| IL-33 | 30 (pro)<br>18 (active) | ST2L<br>IL-1RAcP | Epithelial cells; monocytes; smooth muscle cells; keratinocytes | Promote Th2 cell activation, mast cell activation, and cytokine production |

*Pro forms cleaved to active moieties by proteases including caspase-1, calpain, elastase, and cathepsin G.
†Pro-IL-1α retains bioactivity before cleavage.
DC, Dendritic cell; FLS, fibroblast-like synoviocyte; IL, interleukin; GAG, glycosaminoglycan; iNOS, inducible nitric oxide synthase; MMP, matrix metalloproteinase; NK, natural killer; PG, peptidoglycan; PMN, polymorphonuclear neutrophil; ROI, reactive oxygen intermediates; Th, T helper.

**TABLE 26-2** Tumor Necrosis Factor Superfamily Cytokines* with Potential Role in Rheumatic Disease

| Cytokine | Size (kDa) | Receptors | Major Cell Sources | Selected Functions |
|---|---|---|---|---|
| TNF | 26 (pro) | TNF-RI (p55) | Monocytes; T, B, NK cells; PMNs; eosinophils; mast cells; fibroblasts; keratinocytes; glial cells; osteoblasts; smooth muscle | Monocyte activation, cytokine, and PG ↑ |
| | | TNF-RII (p75) | | PMN priming, apoptosis, oxidative burst ↑<br>Endothelial cell adhesion molecule, cytokine release ↑; fibroblast proliferation and collagen synthesis ↓<br>MMP and cytokine ↑<br>T cell apoptosis; clonal (auto)regulation; TCR dysfunction<br>Adipocyte FFA release ↑<br>Endocrine effects—ACTH, prolactin ↑; TSH, FSH, GH ↓ |
| LTα | 22-26 | TNF-RI | T cells; monocytes; fibroblasts; astrocytes; myeloma; endothelial cells; epithelial cells | Peripheral lymphoid development |
| | | TNF-RII | | Otherwise similar bioactivities to TNF |
| RANK ligand | 35 | RANK | Stromal cells; osteoblasts; T cells | Stimulates bone resorption via osteoclast maturation and activation<br>Modulation of T cell–DC interaction |
| OPG | 55 | RANKL | Stromal cells, osteoblasts | Soluble decoy receptor for RANKL |
| BLyS† | 18-32 | TACI<br>BCMA<br>BLyS-R | Monocytes; T cells; DCs | B cell proliferation, Ig secretion, isotype switching, survival<br>T cell co-stimulation |
| APRIL | – | TACI<br>BCMA | Monocytes; T cells; tumor cells | B cell proliferation<br>Tumor proliferation |

*Additional members of importance include TRAIL, TWEAK, CD70, FasL, and CD40L. At least 18 members of the family are now described.
†Also called B cell activating factor belonging to the TNF family (BAFF).
ACTH, Adrenocorticotropic hormone; APRIL, a proliferation inducing ligand; BCMA, B cell maturation protein; BLyS, B lymphocyte stimulator protein; DC, dendritic cell; FFA, free fatty acid; FSH, follicle-stimulating hormone; GH, growth hormone; Ig, immunoglobulin; LT, lymphotoxin; MMP, matrix metalloproteinase; NK, natural killer; OPG, osteoprotegerin; PG, peptidoglycan; PMN, polymorphonuclear neutrophil; RANKL, receptor activator of NF-κB ligand; TACI, transmembrane activator and calcium modulator and cyclophilin ligand; TCR, T cell receptor; TNF, tumor necrosis factor; TRAIL, TNF-related apoptosis-inducing ligand; TSH, thyroid-stimulating hormone; TWEAK, TNF-like weak inducer of apoptosis.

**TABLE 26-3** Cytokines Associated Predominantly with Effector Function for T Cells*

| Cytokine | Size (kDa) | Receptors | Major Cell Sources | Key Functions |
|---|---|---|---|---|

*Additional members of potential importance include IL-11, cardiotropin-1, and ciliary neurotrophic factor. Note overlapping effects within family.
†Membrane or soluble form can dimerize gp130 to promote signaling, which promotes signal transduction.
gp130, Glycoprotein 130; IL, interleukin; LIFR, leukemia inhibitory factor receptor; OMR, oncostatin M receptor; TIMP, tissue inhibitor of metalloproteinase; TNF, tumor necrosis factor.

**TABLE 26-7** Growth Factors Relevant to Rheumatic Diseases

| Cytokine | Receptors | Cellular Sources | Key Functions |
|---|---|---|---|
| TGF-β* | Type I TGFβR | Broad—including fibroblasts, monocytes, T cells, platelets | Wound repair, matrix maintenance, and fibrosis |
| Isoforms 1-3† | Type II TGFβR<br>Others | | Initial activation then suppression of inflammatory responses<br>T cell (Treg and Th17) and NK cell proliferation and effector function ↓<br>Early-phase leukocyte chemoattractant, gelatinase, and integrin expression ↑<br>Early macrophage activation then suppression, reduced iNOS expression |
| BMP family (BMP2-15) | BMPRI<br>BMPRII | Varied (e.g., epithelial and mesenchymal embryonic tissues); bone-derived cell lineages | Regulate critical chemotaxis, mitosis, and differentiation processes during chondrogenesis and osteogenesis, tissue morphogenesis (e.g., heart, skin, eye) |
| PDGF | PDGFRα<br>PDGFRβ | Platelets; macrophages; endothelial cells; fibroblasts; glial cells; astrocytes; myoblasts; smooth muscle cells | Local paracrine or autocrine growth factor for variety of lineages<br>Wound healing |
| FGF family | FGFR (various)<br>Basic FGF<br>Acidic FGF | Widespread | Growth and differentiation of mesenchymal, epithelial, and neuroectodermal cells |

*Members of TGF-β superfamily include BMP, growth and differentiation factor, inhibinA, inhibinB, müllerian inhibitory substance, glial-derived neurotrophic factor, and macrophage inhibitory cytokine.

†Bound to latency-associated peptide to form small latency complex and to latent TGF-β binding protein to form large latent complex; activated by proteolytic and nonproteolytic pathways.

BMP, Bone morphogenetic protein; FGF, fibroblast growth factor; iNOS, inducible nitric oxide synthase; NK, natural killer; PDGF, platelet-derived growth factor; TGF, transforming growth factor; Th, T helper; Treg, regulatory T cell.

**TABLE 26-8** Miscellaneous Cytokines with Potential Roles in Rheumatic Diseases

| Cytokine | Size (kDa) | Receptors | Cellular Sources | Key Functions |
|---|---|---|---|---|
| MIF | 12 | Unclear | Macrophages; activated T cells; fibroblasts (synoviocytes) | Macrophage cytokine release, phagocytosis, NO release ↑<br>T cell activation; DTH<br>Fibroblast proliferation; COX expression; $PLA_2$ expression<br>Intrinsic oxidoreductase activity ("cytozyme") |
| HMGB1 | 30 | RAGE, dsDNA<br>Others (?) | Widespread expression; necrotic cells; macrophages; pituicytes | DNA-binding transcription factor<br>Necrosis-induced inflammation<br>Macrophage activation—delayed pro-inflammatory cytokine<br>Smooth muscle chemotaxis<br>Disrupts epithelial barrier function<br>Bactericidal (direct) |
| GM-CSF | 14-35 | GM-CSFRα<br>GM-CSFRβ | T cells; macrophages; endothelial cells; fibroblasts | Granulocyte and monocyte maturation; hemopoietic effects<br>Leukocyte PG release; DC maturation<br>Pulmonary surfactant turnover |
| G-CSF | 19 | G-CSFR | Monocytes; PMNs; endothelial cells; fibroblasts; various tumor cells; stromal cells | Granulocyte maturation; promotes PMN function |
| M-CSF | 28-44 | M-CSFR | Monocytes; fibroblasts; endothelial cells | Monocyte activation, maturation |
| IL-32α-δ | Unknown | Unknown | Monocytes; T cells; NK cells; epithelial cells | Promotes pro-inflammatory cytokine release from variety of cells |
| Type I interferons IFNα/β family | Various | IFNαβR | Widespread | Anti-viral response<br>Broad immunomodulatory effects (promotes MHC expression)<br>Macrophage activation; lymphocyte activation and survival<br>Anti-proliferative, cytoskeletal alteration, differentiation ↑ |

COX, Cyclo-oxygenase; DC, dendritic cell; dsDNA, double-stranded DNA; DTH, delayed-type hypersensitivity; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HMGB, high mobility group box chromosomal protein; IFN, interferon; M-CSF, macrophage colony-stimulating factor; MHC, major histocompatibility complex; MIF, macrophage inhibitory factor; NO, nitric oxide; PG, prostaglandin; PLA, phospholipase A; PMN, polymorphonuclear neutrophil; RAGE, receptor for advanced glycation end products.

## Cytokines in Chronic Inflammation

Cytokines critically modulate the cellular interactions that characterize chronic inflammation. Studies using real-time image analytic techniques such as two-photon microscopy and confocal scanning suggest continuous cellular motility during inflammation. Inflammatory lesions might properly be considered fluid states in which individual cells under cytokine control transiently contribute to organized functional subunits—such as the ectopic germinal center, synovial lining layer, or renal interstitial nephritis—yet remain competent to migrate thereafter under the influence of chemotactic gradients on the extra-cellular matrix. Cytokines also may promote cell death (apoptosis) either by withdrawal (e.g., IL-2, IL-7, IL-15, and type I IFNs) or by binding cytokine receptors containing death domains (e.g., TNF-R1). Cytokines contribute at every stage of inflammatory lesion development in a dynamic equilibrium, rather than in a static, linear manner. Chronic inflammation in rheumatic disease usually contains cytokine activities reminiscent of innate and acquired immune responses. For convenience, cytokines can be considered by their effect on cell subsets and cellular interactions (Figure 26-2 describes the role of cytokine activity in a developing and chronic lesion). It is critical to recall that cytokines can contribute both pro- and anti-inflammatory effects dependent on the time and context of their expression.

### T Cell Effector Function in Chronic Inflammation

T cells depend on cytokine function at every developmental stage from bone marrow stem cell maturation, through thymic education, to functional determination and maturation after primary or secondary antigen exposure (see the detailed overview in Chapter 12). The latter is of prime importance because re-education of phenotypic T cell responses may be achieved through alteration of the ambient cytokine milieu. T cell receptor–peptide–major histocompatibility complex (MHC) interactions during T cell–dendritic cell interaction rely on co-stimulatory molecule and local cytokine expression to determine functional outcome (see Tables 26-3 and 26-4). IL-12, in the presence of IL-18, promotes type 1 phenotypic development, characterized ultimately by IFN-γ producing T helper (Th) type 1 effector cells.[20] IFN-γ drives macrophage priming and activation and adhesion molecule expression and promotes granuloma formation and microbial killing. IFN-γ has a complex role in tissue destruction, however, with contradictory data obtained in inflammation models in IFN-γ-deficient and IFN-γ receptor–deficient mice. IFN-γ ultimately may retard tissue destruction, perhaps by suppressing osteoclast activation.[21]

A T cell subset has been defined that secretes IL-17A predominantly (Th17 effector cells), together with IL-22 that is increasingly recognized to be critical in a number of autoimmune diseases. Th17 cells are generated in the presence of IL-6 and transforming growth factor (TGF)-β, expanded by IL-1β and IL-23, and antagonized by IL-25 (IL-17E), IL-10, and, paradoxically, by IFN-γ. IL-17A provides a direct and rapid route to tissue damage via such means as neutrophil recruitment and activation, chondrocyte activation, keratinocyte activation, osteoclast activation, or fibroblast-like synoviocyte (FLS) activation.[22] The precise contribution of Th17 cells in human autoimmune disease is emerging; other lineages, such as innate lymphoid cells, likely also contribute to pathogenesis. Persuasive data from rodent models indicate that Th17 cells may be of primary importance as initiator and effector cells. Clinical trials that target IL-17A are ongoing in various rheumatic diseases, and phase II and III data now clearly demonstrate a pivotal role in psoriasis, psoriatic arthritis, and spondyloarthritis. The role for IL-17A in RA is much less clear because selective inhibitors have limited benefit in that disease.

IL-4 dominance during T cell–dendritic cell interactions in the presence of IL-18 leads to type 2 responses, which promote humoral immunity driven by Th2 cells synthesizing primarily IL-4, IL-5, IL-10, and IL-13. Resulting pathogenesis more likely may be B cell mediated. Cytokines that predispose to regulatory T cell development are unclear, although high levels of IL-10 or TGF-β have been suggested in this context.[23] Effector T cells can operate via secretion of cytokines to patterns determined by their prior activatory conditions.

### Cell-to-Cell Interactions

In many inflammatory lesions, there is relative paucity of inducer T cell–derived cytokines (especially IL-17A or IFN-γ), despite abundant pro-inflammatory cytokine expression. Cell-cell membrane interactions between leukocyte subsets and between tissue cells and leukocytes have emerged as a dominant mechanism sustaining chronic inflammation. Cytokines contribute to these interactions at several levels, including directly as membrane-expressed ligands, indirectly via activating cells, and synergistically by enhancing their subsequent cognate activities. The importance of cytokine–cell contact interactions is best studied in synovial tissues but applies to many inflammatory lesions. Many data now show that cognate interactions between T cells and adjacent macrophages constitute a major pathway driving cytokine release and that cytokines sustain this pathway. Such interactions do not depend on T cell receptor–mediated T cell activation and provide a route to expansion of inflammation by T cells independent of local autoantigen recognition.

Vey and colleagues[24] first observed monocyte activation via cell contact with mitogen-stimulated T cells. Freshly isolated synovial T cells activate macrophages by this mechanism, confirming that contact-induced cellular activation is a fundamental property of inflammatory T cells.[25] Antigen-independent, cytokine-mediated bystander activation confers this capacity on human $CD4^+$ memory T cells.[26] Studies using synovial T cells from RA and psoriatic arthritis tissues reveal that exposure of memory T cells to synergistic combinations of cytokines are most potent in this respect, particularly IL-15, TNF, and IL-6.[27,28] Cytokine activities also operate directly on macrophages to synergize with T cell contact. IFN-γ and IL-18 are most potent in this respect, acting via increased adhesion molecule expression.

Activated memory $CD4^+$ and $CD8^+$ T cells promote cytokine release from macrophages via diverse membrane ligands including leukocyte function-associated antigen-1 (LFA-1)/ intercellular adhesion molecule-1 (ICAM-1),

CD69, and CD40/CD154.[27,29] After contact with T cells, macrophages release increased concentrations of TNF and IL-1, but not IL-10, and they exhibit reduced levels of IL-1Ra. Th1 cells promote relatively greater pro-inflammatory cytokine release than do Th2 cells after co-culture. This finding suggests that their functional phenotype extends beyond cytokine secretion to include a differential membrane receptor array.[30] This suggestion is borne out further in the relative phenotypic distinctions between Th1 (CD40L, CCR5, and IL-18Rα) and Th2 (IL-33R/ST2 and CXCR3) cells. Recent data suggest that Th17 cells can also participate in similar cell-cell interactions. Signaling pathways engaged in monocytes after such T cell–membrane interactions are distinct from the pathways activated by conventional cytokine-inducing agents. Distinct use of phosphatidylinositol 3-kinase, NF-κB, and p38 mitogen-activated protein kinase (MAPK) pathways is observed.[31] Similarly, discrete macrophage signals follow contact with cytokine-activated T cells (which resemble synovial T cells) compared with T cell receptor–activated T cells.[32] Such distinctions offer therapeutic potential in targeting cytokine-activated, T cell–driven pathways, leaving antigen-driven responses relatively intact. The activation state of memory T cells necessary for the previously discussed interactions to proceed remains controversial. Purified resting T cell subsets activate synovial fibroblasts to release IL-6, IL-8, matrix metalloproteinase 3 (MMP-3), and prostanoids, in synergy with IL-17.[33]

It is likely that T cells are activated by interactions with diverse moieties, including extra-cellular matrix components and, potentially, autoantigens. Nevertheless, it is now clear that cytokines can promote chronicity by activating T cells to promote inflammation regardless of local (auto) antigen recognition and that this mechanism has enormous therapeutic potential.

## Agonist/Antagonist Cytokine Activities in Chronic Inflammation

Complex regulatory interactions exist to suppress ongoing inflammatory responses. This suppression is often achieved via parallel secretion of antagonistic cytokines and soluble receptors to regulate cytokine effector pathways. Th1 responses are suppressed partly by cytokines of Th2 type (e.g., IL-4 and IL-10), and consequently, exaggerated Th1 responses arise in models in which the Th2 response is deficient.[20] Th1 and Th2 cells similarly limit Th17 cell expansion.[22] Similar regulatory loops operate for other leukocytes, exemplified by the yin-yang effects of TNF and IL-10 on macrophage cytokine release and effector function.[34]

Inhibitory cytokine activities are usually defined with respect to a pro-inflammatory cytokine, and in other contexts they may have quite distinct functions, rendering prediction of their net contribution to an inflammatory response difficult. IL-10 opposes many of the pro-inflammatory effects of TNF and IL-1β (e.g., it reduces adhesion molecule expression, MHC expression, and MMP release), but it potently activates B cell activation and immunoglobulin secretion.[34] Similarly, TNF, which is normally considered a pro-inflammatory moiety, may have an important role in regulating T cell function because T cells removed from sites of chronic inflammation exhibit suppressed capacity to signal via their T cell receptor that recovers on TNF neutralization.[35] Such regulation is complicated further by the precise ratio of cytokine to soluble receptor such as TNF to sTNF-R or IL-10 to sIL-10R within the local environment. Commensurate with this, administration of anti-inflammatory cytokines such as IL-4, IL-10, and IL-11 has generally proved disappointing in the context of clinical inflammatory diseases. Suppressed IL-10 production might be one unanticipated effect of p38 MAPK inhibitors, with efficacy of these agents and underscoring the importance of considering the complex interplay between pro-inflammatory and anti-inflammatory cytokines. An important caveat is the potential requirement of combinations of cytokines to suppress inflammation optimally (e.g., combinations including IL-4, IL-10, and IL-11). Further functional antagonism is exemplified in the antagonistic activities of IL-1β and IL-1Ra and of IL-18 and IL-18 binding protein in regulating macrophage activation.

The role of cytokines in regulating cognate interactions between leukocytes has emerged more recently. Although anti-inflammatory pathways are poorly induced after cell contact, cytokine-activated T cells can induce IL-10 release by monocytes.[32] RA synovial membrane IL-10 release, which is partially T cell dependent, feeds back to regulate TNF release. Cytokine production from adjacent cell lineages within an inflammatory lesion may also be suppressive. IFN-β reduces mitogen-activated, T cell–induced macrophage release of TNF and IL-1, whereas IL-1Ra release is enhanced,[36] thus providing a mechanism whereby type I IFNs could modify pro-inflammatory cytokine production. Regulation extends beyond conventional cytokine activities. Prostaglandins and lipoprotein moieties, particularly high-density lipoprotein, can suppress cytokine-mediated, T cell–macrophage interactions.[37]

## Disease-Modifying Anti-rheumatic Drugs

Conventional disease-modifying anti-rheumatic drugs can also act via modulation of cytokine production. Methotrexate modulates release of various cytokines in vitro, in part mediated via the adenosine–cyclic adenosine monophosphate pathway.[38] The active metabolite of the dihydroorotate dehydrogenase inhibitor leflunomide, A77 11726, reduces TNF, IL-1β, IL-6, and MMP-1, but it does not reduce IL-1Ra release by monocytes after mitogen-activated T cell contact.[39,40] Leflunomide may mediate these activities through modulation of inhibitor of NF-κB (IκB)α phosphorylation and degradation and AP-1 and c-Jun N-terminal protein kinase activation.[41] Sulfasalazine is an inhibitor of pro-inflammatory cytokine-induced NF-κB. Biologic agents also potently modify cytokine expression in a variety of disease states. Signal transduction inhibitors such as agents that inhibit Janus kinase (JAK) or spleen tyrosine kinase (SYK) not only inhibit cytokine action but also the subsequent production of additional cytokines that can exacerbate disease.

## Cellular Interactions Across Diverse Tissues

Cytokines promote cognate cellular interactions across a range of tissues. In contrast to T cell–macrophage and T

cell–dendritic cell interactions, in which adhesion molecule and co-stimulatory pathways are often implicated, cell-cell membrane communications apart from leukocyte-leukocyte interactions are often mediated through membrane cytokine expression. T cell contact–mediated activation of fibroblasts operates via membrane TNF and IFN-γ to enhance fibroblast cytokine release and MMP—but not tissue inhibitors of metalloproteinase—expression, favoring tissue destruction.[29] The source and activation status of the fibroblast are vital; fibroblast-like synoviocytes, but not cutaneous fibroblasts, are potently activated by this route. Other studies have shown T cell contact–mediated activation of neutrophils, keratinocytes, mesangial cells (via a combination of membrane cytokine and CD40L expression), platelets, and renal tubule epithelial cells. Cytokine-activated macrophages (via IFN-γ and sCD40L) may interact via cell contact with mesangial cells to activate adhesion molecule and chemokine release by the latter. Cell-cell contact between cells of the immune system and beyond likely represents a ubiquitous mechanism whereby perpetuation of chronic inflammation is potently influenced by local production of cytokines.

### B Cells and Cytokine Release in Chronic Inflammation

Cytokines are crucial to B cell maturation, proliferation, activation, isotype switching, and survival (see Chapter 14). Cytokine-mediated B cell activation is important in immune complex generation, B cell antigen presentation, B cell–T cell interactions, and germinal center formation. Particular importance has been placed on the TNF superfamily cytokines, B-lymphocyte stimulator (BLyS) and a proliferation-inducing ligand (APRIL). These cytokines are crucial for B cell development, survival, and optimal activation. However, their hierarchical place is now disputed at least in terms of RA biology because clinical targeting of both using atacicept (which neutralizes both BLyS and APRIL) has proven inefficacious in RA. Neutralization of BLyS with a monoclonal antibody has been similarly disappointing in RA, although more promising data have emerged in the treatment of systemic lupus erythematosus (SLE). B cells in turn represent a potent source of cytokines such as IL-6 and IL-10. The latter has now attracted much attention with the identification of B regulatory cells delineated by their dominant IL-10 expression. B cells also have been considered important inducers of macrophage-derived cytokine release. This process may operate primarily via immune complex formation[42] or through regulation of T cell activation (with B cell help). Complex regulatory feedback loops involving cytokine expression and B cells are likely important in a range of rheumatic diseases in which B cells are of paramount pathophysiologic importance. This may be one core mechanism whereby B cell depleting strategies in rheumatic diseases (e.g., via use of rituximab) are mediating their effects.

### Innate Cell Lineages in Chronic Inflammation

Cytokines potently activate innate response cells that contribute to the chronic inflammatory lesion of a variety of rheumatic diseases. Tables 26-1 through 26-8 document relevant examples in which neutrophils, NK cells, eosinophils, and mast cells may be recruited and activated by the presence of appropriate cytokine combinations.

### Growth Factors in Chronic Inflammation

Many data document the importance of growth factor families in chronic inflammation. TGF-β superfamily members including TGF-β isoforms and bone morphogenetic protein family members warrant particular reference. TGF-β is critically involved in processes of cell proliferation, differentiation, inflammation, and wound healing.[43] Bone morphogenetic proteins, in addition to regulating inflammatory responses, are paramount in determining cartilage and bone tissue development and remodeling.[44] As such, they are of increasing interest in the pathogenesis of several rheumatic diseases.

## CYTOKINE EFFECTS BEYOND IMMUNE REGULATION

A striking feature of the cytokine field concerns the broad functional pleiotropy exemplified in the effects of cytokines in normal physiologic and adaptive processes. Cytokine activities are found in muscle, adipose tissue, central nervous system, and liver, mediating normal regulation of metabolic pathways and modulation imposed by altered tissue conditions. Examples are found not only in the release of adipokines that regulate adipose metabolic pathways but also in the release of conventional cytokines by fat pads in inflammatory synovitis. Because cytokines thereby likely mediate normal and pathophysiologic activities in many tissues, it is increasingly recognized that they may underlie the co-morbidity that is observed in vascular, central nervous system, and bone tissues in several rheumatic diseases. Thus cytokines or their receptors arising from the primary target tissues (e.g., joint and kidney) may "leak" into the circulation and promote additional pathology in other tissues. Commensurate with this targeting, such cytokines may modulate this co-morbid risk, which is now exemplified in the reduction of vascular morbidity in patients receiving TNF blockers. However, paradoxical effects occur—for example, tocilizumab inhibits IL-6R, and in so doing it elevates total and low-density lipoprotein cholesterol. The long-term implications of this effect for vascular risk are not yet clear but provide abundant evidence for complex interactions between cytokine and metabolic processing.

## CONCLUSION

Cytokines represent a diverse family of glycoproteins that are active across a broad range of tissues. Their pleiotropic functions and propensity for synergistic interactions and functional redundancy render them intriguing therapeutic targets. Thus far, single cytokine targeting has proved useful in several rheumatic disease states. Further elucidation of the biology and functional interactions within this expanding family of bioactive moieties is likely to prove informative in resolving pathogenesis and in generating novel therapeutic options. In particular, biologic agents that target cytokines will increasingly unravel a novel molecular taxonomy for the rheumatic diseases.[45-47]

CHAPTER 27

# Principles of Signaling

Vaishali R. Moulton • Abel Suarez-Fueyo • Sean Bradley • George C. Tsokos

**KEY POINTS**

- Cells of the immune system sense environmental stimuli via receptors, which may be expressed on the cell surface or may be intra-cellular.
- Interaction of ligands with receptors initiates signaling cascades, which relay the extra-cellular stimuli within the cell and alter cellular function.
- Signaling pathways typically involve phosphorylation (kinases) and dephosphorylation (phosphatases) of molecules.
- Signaling eventually leads to cellular responses such as changes in growth, activation, proliferation, and differentiation.

Immune cells respond to a vast variety of stimuli to carry out their role in maintenance of the immune system. Physiologic and innocuous and foreign or dangerous signals must be recognized and communicated within the cell, where they culminate into cellular responses such as changes in shape, motility, growth, activation, differentiation, or production of effector molecules. Distinct cascades of interacting molecules connect the perceived stimuli and relay information into the cytosol and/or nucleus to initiate these effector functions either directly or through initiation of gene transcription and protein translation programs. Signaling pathways can be categorized based on the mechanisms by which environmental stimuli are sensed, such as cell surface receptor-mediated interactions or intra-cellular detection of lipid-soluble molecules. Receptor-mediated signaling can further be classified by the presence or absence of enzymatic activity. This chapter focuses on fundamental concepts of signaling based on these groups of receptors and their intra-cellular signaling pathways.

## RECEPTORS WITH ENZYMATIC ACTIVITY

Many ligands are water soluble and therefore impermeable through the lipid bilayer of the plasma membrane, and interact with cognate receptors on the cell surface. These ligands include antigens, immune complexes, chemokines, cytokines, and microbial components. Interactions of ligands with their receptors initiate downstream catalytic activity and recruitment of similar signaling molecules or adaptor molecules. Receptors with enzymatic activity comprise extra-cellular ligand-binding domains, membrane-spanning domains, and intra-cellular signaling domains. Intrinsic enzymatic activity within the receptor includes kinase, phosphatase, or guanylate cyclase activity.

The receptor tyrosine kinase (RTK) family is a common class of these receptors. The human RTK family consists of 20 subfamilies that detect ligands such as stem cell factor, insulin, epidermal growth factor (EGF), vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), colony-stimulating factor (CSF), and fibroblast growth factor (FGF).[1] These receptors are generally inactive until bound by their ligands, which induce clustering and dimerization of the receptors and autophosphorylation of their kinase domains (Figure 27-1A). Upon activation, other kinases or cytoplasmic molecules are recruited for activation and transmission of signals downstream. In addition to receptor binding, ligands, along with accessory molecules, may also mediate receptor dimerization. FGF, for example, partners with heparin sulfate proteoglycans to cross-link and dimerize FGF receptors (FGFR).[2] Some receptors may dimerize even in the absence of ligands, such as the disulfide-linked insulin receptor and the insulin-like growth factor (IGF)-1 receptors. Ligand binding induces structural changes to activate these receptors and signaling by diverse mechanisms.[1]

Phosphorylation occurs at tyrosine, serine, or threonine residues. The phosphotyrosine is recognized by proteins containing Src homology (SH)2 and phosphotyrosine-binding (PTB) domains. These proteins may be kinases or phosphatases or lack enzymatic activity and act as intermediates known as *adaptor proteins*. SH2 domain proteins include phospholipase Cγ (PLCγ), phosphatidyl inositol-3-OH kinase (PI3K), and SHP phosphatases. Grb-2 and SHP2 are examples of adaptor proteins, of which Grb-2 recruits the guanine nucleotide exchange factor (GEF) SOS. SOS activates the small G protein Ras to activate the mitogen-activated protein kinase (MAPK) pathway. In addition, RTKs can activate PI3K, which activates the formation of phosphatidylinositol-3,4,5-triphosphate ($PIP_3$). PLCγ is also phosphorylated and activated by RTKs, leading to hydrolysis of phosphatidylinositol-4,5-$P_2$ ($PIP_2$) to generate inositol-1,4,5-triphosphate ($IP_3$) and diacylglycerol (DAG).

Transforming growth factor-beta (TGF-β) is an anti-inflammatory cytokine, which binds to receptors similar to the RTK family and regulates a variety of cellular processes.[3] The TGF-β ligand superfamily includes bone morphogenetic proteins, growth and differentiation factors (GDFs), activin, and TGF-β1, 2, and 3. TGF-β binding to a type II receptor that bears a serine threonine kinase mediates phosphorylation of a type I receptor to form a heterotrimeric complex with the ligand. This complex recruits and phosphorylates the intra-cellular SMAD proteins. The SMAD proteins include the receptor Smads 1, 2, 3, 5, and

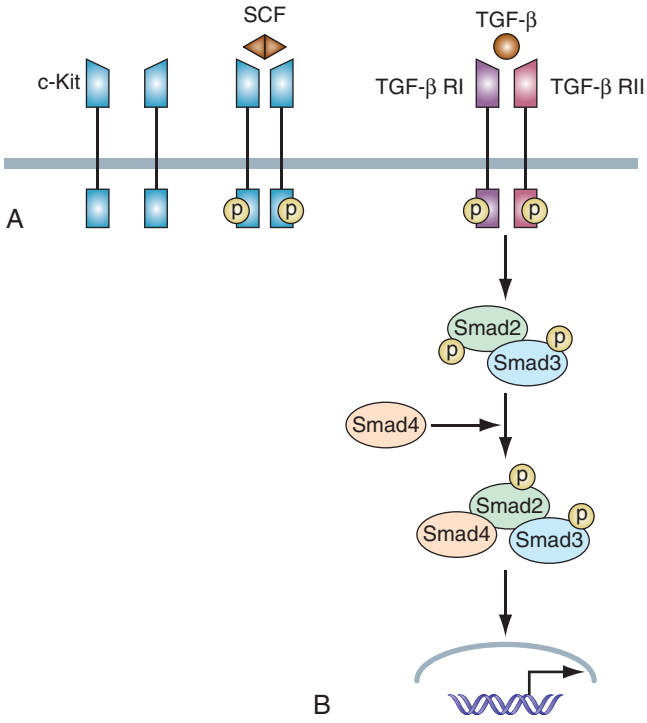

**Figure 27-1** **A,** Receptor tyrosine kinase c-kit, the receptor for stem cell factor (SCF) is depicted in the inactive form as monomers *(left)*. Upon binding to its ligand, the receptor dimerizes and the kinase domains phosphorylate each other *(right)*. **B,** Schematic depicting the transforming growth factor (TGF)-β–TGFβR signaling pathway. P, Phosphate.

9. Once phosphorylated, the r-Smads 2 and 3 oligomerize with a common mediator, Smad4, and translocate to the nucleus to regulate gene transcription (Figure 27-1B).[4]

Some receptors have phosphatase activity, such as protein tyrosine phosphatases (PTP). For example, the Src family kinases contain an activating and an inhibitory tyrosine residue. C-terminal Src kinase (Csk) phosphorylates the inhibitory tyrosine, whereas the transmembrane tyrosine phosphatase CD45 removes this phosphate, which is required for initiation of signaling in lymphocytes.

## RECEPTORS THAT RECRUIT MOLECULES WITH ENZYMATIC ACTIVITY

### Cytokine Receptors

Cytokines are soluble peptide regulators with profound effects on immune homeostasis and autoinflammatory disease.[5] Cytokine receptors are organized into four classes on the basis of their domain and structure.

1. Class I receptors are characterized by a WSXWS motif and can be subdivided on the basis of structural homology or the use of shared signaling subunits. Examples include receptors for interleukin (IL)-2, IL-6, IL-7, IL-15, and also for hormones such as erythropoietin and prolactin.[6]
2. Class II receptors include those for type I and II interferon (IFN), IL-10, IL-20, IL-22, IL-26, IL-28, and IL-29.[7]
3. Tumor necrosis factor (TNF) receptors share structures with some noncytokine receptors, such as CD95.[8]
4. IL-1 receptors can be considered analogous to Toll-like receptors (TLRs).[9]

These receptor complexes present two or more single-pass transmembrane subunits that include domains that recruit signaling proteins upon activation, and subunits with extra-cellular binding domains. Whereas class I and II cytokine receptors use the Janus kinase (JAK)/signal transducer and activator of transcription (STAT) signaling pathway, TNFRs use adaptor molecules called *TNFR-associated factors* (TRAFs) to recruit complexes with different functions.

### JAK/STAT Pathway

The mammalian JAK family includes four tyrosine kinases: JAK1, JAK2, JAK3, and tyrosine kinase 2 (Tyk2) (Figure 27-2). All four proteins have a conserved kinase domain and a related pseudokinase regulatory domain. JAK1 and JAK2 are involved in a wide range of cellular functions in growth and development, hematopoiesis, and inflammation, whereas JAK3 and Tyk2 are primarily important in the immune response. JAKs are controlled predominantly by post-translational mechanisms. More than 30 class I cytokine receptors and approximately 12 class II cytokine receptors activate the JAK family members. JAK structure is distinct from other tyrosine kinases. The N-terminal of these proteins contains two domains: an SH2 domain and a band 4.1 ezrin radixin moesin (FERM) domain. Interestingly, however, the SH2 domains do not function as phosphotyrosine residues but instead act as scaffolds. Upon cytokine-receptor binding, JAKs are reciprocally activated by phosphorylation, and phosphorylate receptor cytoplasmic tail regions. This leads to recruitment and activation of SH2 domain-containing proteins known as the *STAT*s (STAT1, 2, 3, 4, 5A, 5B, and 6). The STAT proteins share a high homology in their SH2 domain: a DNA-binding domain and a transactivation domain. STATs bind to the phosphorylated receptor through their SH2 domain and are activated in response to phosphorylation by JAKs. Upon phosphorylation, STATs undergo conformational changes, detach from the receptor, and dimerize with another STAT molecule. Dimers may be homo- or heterodimers, which subsequently translocate to the nucleus to regulate gene expression.[10,11]

Different STATs are important for signaling of distinct cytokines and/or growth factors/hormones (see Figure 27-2). In addition to the STAT proteins, JAK activation also leads to recruitment of SHP2 and Shc, p85, and SOCS3, which leads to regulation of Ras/MAPK and PI3K cascades. STAT proteins continually traffic between the cytoplasm and nucleus to mediate their function as transcription factors.[12] However, not all STATs travel in the same manner. STAT1 and STAT4 entry into the nucleus depends on their tyrosine phosphorylation and, importantly, dimerization, which creates a nuclear localization signal. Unphosphorylated STAT2 is constantly imported into the nucleus in complex with interferon regulatory factor (IRF)-9, but is shuttled back into the cytoplasm because of its dominant nuclear export signal. After phosphorylation, it can dimerize with STAT1 to import the complex into the nucleus. STAT3, 5, and 6 are continually imported to the nucleus regardless of their tyrosine phosphorylation state.

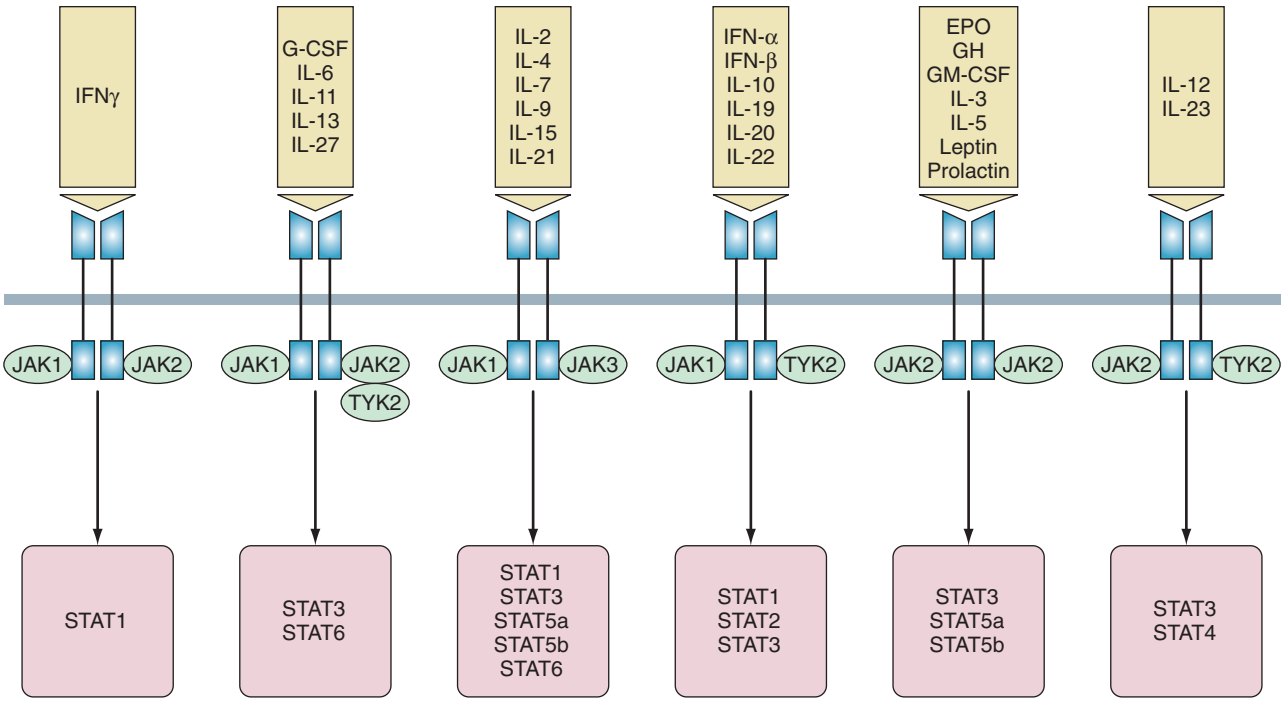

**Figure 27-2** Janus kinase (JAK)/signal transducer and activator of transcription (STAT) pathway. Activation of different JAK/STAT combinations by major cytokines. Cytokine receptors recruit and activate specific pairs of JAK kinases, which induce STAT phosphorylation and dimerization. STAT dimers translocate into the nucleus, where they act as transcription factors. EPO, Erythropoietin; G-CSF, granulocyte-colony stimulating factor; GH, growth hormone; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin.

Cytokine responses and the JAK-STAT pathway are under tight control of molecules, including protein tyrosine phosphatases (PTPs), protein inhibitor of activated STATs (PIAS), and suppressor of cytokine signaling (SOCS) proteins.[13] PTPs include SH2-containing PTP1 (SHP1), SHP2, CD45, and T cell PTP (TCPTP). The PTP and PIAS proteins, although not exclusive regulators of the JAK-STAT pathway, also regulate other cellular functions. PIAS inhibit the STATs by interfering with their DNA binding function and also, likely, by recruiting histone deacetylases. The suppressor of SOCS family consists of eight members: SOCS 1-7 and cytokine-induced STAT inhibitors (CISs), which block STAT activation. SOCS3 acts mainly by binding to the JAK and the cytokine receptor, which leads to inhibition of STAT3 activation, Besides STAT3, SOCS3 can also regulate signaling through other STATs. SOCS3 can either inhibit JAK activation or lead to ubiquitin-proteasome–mediated degradation of the receptor.

## Tumor Necrosis Factor Receptor Signaling

The TNF superfamily consists of 19 ligands and 29 receptors, which play varied roles in inflammation, apoptosis, and proliferation.[14] TNF members generally have pro-inflammatory functions mediated in part through the nuclear factor-κB (NF-κB) pathway. TNF and lymphotoxin-α (also known as *TNFβ*) were the first two members identified, and share approximately 50% homology in their protein sequence. Other members of this superfamily include lymphotoxin-β, CD40L, FasL, CD30L, 4-1BBL, CD27L, OX40L, TNF-related apoptosis-inducing ligand (TRAIL), lymphotoxin-like ligand competitive with gD-1 HSV for HVEM expressed on T cells (LIGHT), receptor activator of NF-κB ligand (RANKL), TNF-related weak inducer of apoptosis (TWEAK), a proliferation-inducing ligand (APRIL), B cell–activating factor (BAFF), vascular endothelial cell-growth inhibitor (VEGI), ectodysplasin A (EDA)-A1, EDA-A2, and glucocorticoid-induced TNF receptor (TNFR) family ligand (GITRL) .

TNF binds to two distinct receptors: TNFR1 and TNFR2 (Figure 27-3). Receptors of the TNF superfamily can be categorized based on the presence or absence of an intracellular death domain (DD), of which the D-containing receptors are ubiquitous in expression. TNFR1 contains a DD and is expressed in virtually all cell types, whereas TNFR2 is expressed mainly on immune cells, endothelial cells, and nerve cells. TNF is expressed both in soluble form and as a transmembrane protein on the cell surface, whereas lymphotoxin-α is only expressed as soluble protein. TNF signaling induces several signaling pathways, including activation of NF-κB, MAPK, and apoptosis. Upon TNF binding to the TNFR1, the DD recruits the TNFR-associated death domain (TRADD) protein, which subsequently recruits the Fas-associated protein with death domain (FADD). This triggers activation of caspase 8 and caspase 3, leading to apoptosis. TNF may also activate apoptosis through the mitochondrial pathway, cytochrome C release, and activation of caspase 9 and caspase 3. On the other hand, TNF can activate NF-κB, leading to cell survival and proliferation. This pathway involves TNF binding to TNFR1 and recruitment of TRADD, followed by TNFR-associated factor 2 (TRAF2/TRAF5), receptor-interacting protein

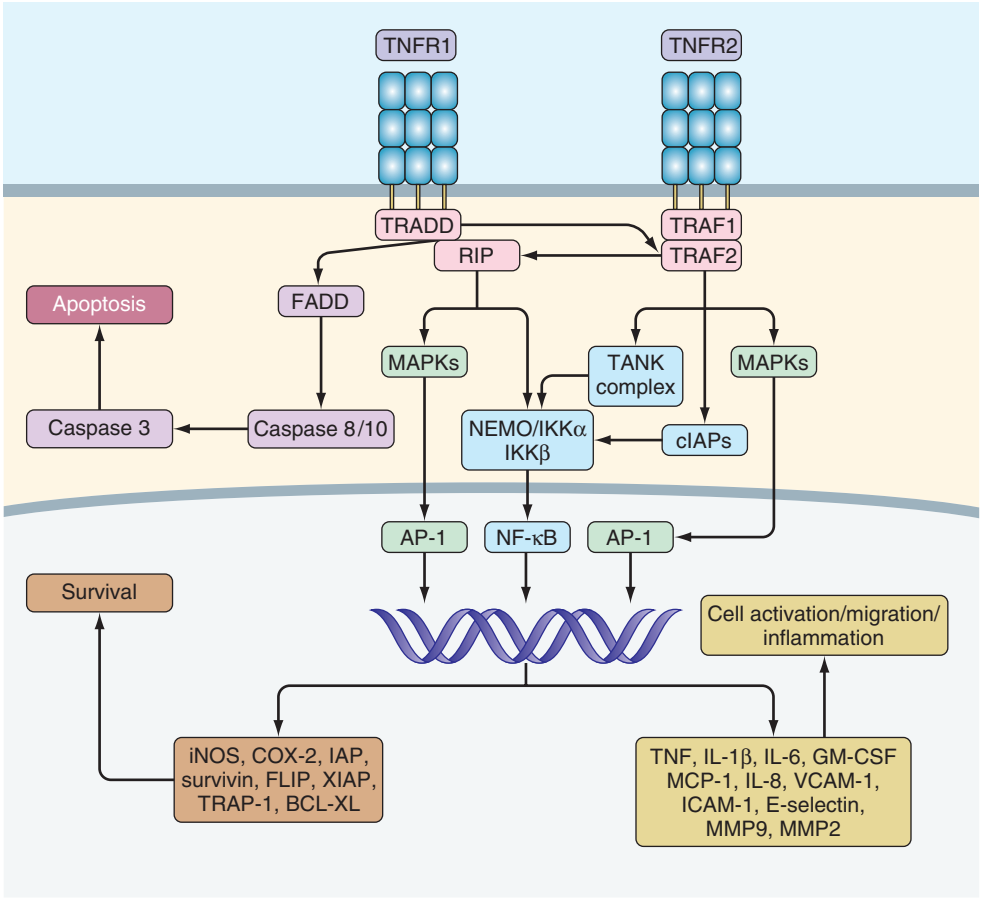

**Figure 27-3** Tumor necrosis factor receptor 1 (TNFR1) and TNFR2 signaling pathways. AP, Activator protein; BCL, B cell lymphoma; cIAPs, cellular inhibitors of apoptosis; COX, cyclooxygenase; FADD, Fas-associated protein with death domain; FLIP, FLICE-like inhibitory protein; GM-CSF, granulocyte-macrophage colony-stimulating factor; IAP, inhibitor of apoptosis; ICAM, intercellular adhesion molecule; IKK, IκB (inhibitor of κB) kinase; IL, interleukin; iNOS, inducible nitric oxide synthetase; MAPK, mitogen-activated protein kinases; MCP, monocyte chemotactic protein; MMP, matrix metalloproteinase; NEMO, NF-κB essential modulator; NF-κB, nuclear factor-κB; RIP, receptor-interacting serine/threonine-protein kinase 1; TANK, TRAF family member-associated NF-κB activator; TRADD, tumor necrosis factor receptor type 1–associated death domain; TRAP, TNF receptor-associated protein; VCAM, vascular cell adhesion protein; XIAP, X-linked inhibitor of apoptosis protein.

(RIP), TAK1, and IκB kinase (IKK). IKK, which is the activator of NF-κB, is composed of two catalytic subunits and one regulatory subunit known as *NF-κB essential modulator* (NEMO). NF-κB activation leads to the production of pro-inflammatory cytokines, such as IL-6, IL-18, chemokines, cyclooxygenase 2 (COX2), and 5-lipoxygenase (5-LOX). TNF–TNFR1 signaling regulates proliferation through TRAF2 to activate MEKK1, MKK7, and JNK. p38 MAPK is activated through TRAF2 and MKK3.[14,15] TNFR2 lacks a DD; therefore, how it mediates signaling is not well understood. It can bind TRAF2 directly, indirectly recruit TRAF1, TRAF-associated NF-κB activator (TANK), and cellular inhibitors of apoptosis (cIAPs) and thereby activate the NF-κB pathway. In addition, TNFR2 signaling can also activate the MAPK pathways efficiently. Despite the general belief that TNFR1 signaling induces apoptosis and the TNFR2 pathway is prosurvival, cross-talk exists between the two pathways, and TNFR2 signaling may also lead to apoptosis in some cells, despite the lack of a DD.[16] TNF signaling in addition induces pro-inflammatory cytokines such as IL-6, and extra-cellular matrix-degrading enzymes known as *matrix metalloproteinases* (MMP), which function in cellular activation and migration.

## G Protein–Coupled Receptors

G protein–coupled receptors (GPCRs) are a large family of approximately 350 members that bind a variety of ligands, including hormones, lipids, chemokines, and leukotrienes. They are seven-transmembrane domain-bearing proteins that associate with an intra-cellular trimeric G protein (α, β, or γ) and are organized into five families: rhodopsin, secretin, glutamate, adhesion, and Frizzled/Taste2 (Table 27-1). Ligand binding promotes the exchange of GDP for GTP and dissociation of the Gα and β subunits from the receptor subunit.

Based on their α-subunits, G proteins are divided into four subfamilies: Gαs, Gαi/o, Gαq/11, and Gα12/13. Each Gα has specific targets: Gαs and Gαi/o activate or repress adenyl cyclase (AC), regulating cAMP levels to impact several ion channels and the activation of protein kinase A (PKA), whereas Gαq/11 activates phospholipase C (PLC)-β to generate $IP_3$ and DAG from $PIP_2$, ultimately leading to $Ca^{2+}$ and protein kinase C (PKC) pathway activation. The targets for Gα12/13 are three RhoGEFs that activate the small GTPase Rho, critical for cytoskeleton regulation via the stress-activated MAPK pathway. Alternatively, the

**TABLE 27-1** Examples of G Protein–Coupled Receptors (GPCR) and Their Ligands

| GPCR Superfamily | GPCR Family | GPCR | Ligands |
|---|---|---|---|

| Frizzled/Taste2 | | FZ5 | Wnt5a |

Gβγ-complexes regulate several ion channels, specific isoforms of AC, PLC, and PI3K (Figure 27-4).[17] Gβγ dimers activate the Rho family G proteins to regulate actin filament reorganization and therefore induce cytoskeletal changes and impact cellular trafficking. These changes are important in response to chemokines, anaphylatoxins, or histamine. Sphingosine-1-phosphate (S1P) is a lipid-signaling molecule present in blood and lymph. Its receptor is abundantly expressed on endothelial cells and is important for lymphocytes exiting from the thymus and lymph nodes.

## Immunoreceptors: T Cell Receptor, B Cell Receptor, and FcRs

Immune cells express antigen recognition receptors that are generated and selected for in a complex fashion.[18,19] T cells and NKT cells express T cell receptor (TCR) and recognize peptides or lipids associated with the major histocompatibility complex (MHC), or CD1d, respectively. B cells, through the B cell receptor (BCR), recognize soluble antigens. Lymphoid and myeloid cells, such as NK cells and macrophages, express receptors of the FcR family, which cause activation upon detection of antibodies in complex with antigen. These receptors are heteromultimeric complexes, with a subunit of one or two chains that recognize antigen, (TCRα and TCRβ) and CD3 subunits that have from one to six chains that contain immunoreceptor tyrosine-based activation motif (ITAM) domains (see Figure 27-4).

Antigen recognition triggers the activation of membrane proximal early kinases, including Src, Syk, and Tec. The Src family phosphotyrosine kinases (PTK) comprise eight kinases (Fgr, Fyn, Src, Yes, Blk, Hck, Lck, Lyn). These kinases associate with different receptors in a variety of cells. Upon activation, they undergo autophosphorylation and phosphorylate tyrosines of the ITAM domain. Their function is regulated by the kinase Csk and the protein tyrosine phosphatase CD45.[20-22] ITAM phosphorylation leads to recruitment and activation of Syk family kinases recruited through SH2 domains. BCRs recruit Syk, whereas ZAP-70 binds to phospho-ITAMs of CD3 zeta within the TCR. Both kinases are implicated in the signaling of Fc receptors because Syk associates with their common gamma chain, although some incorporate CD3 zeta to recruit ZAP-70. These then undergo autophosphorylation to create sites for interaction with SH2 proteins.[23]

The Tec family consists of five different kinases (Bmx, Btk, Itk, Tec, and Txk/Rlk), which translocate to the cell membrane through their pleckstrin homology (PH) domain to bind $PIP_3$. Alternatively, they are recruited via their SH2 domains, which recognize ITAM motifs on adaptor proteins (e.g., BLNK in B cells, or SLP-76 and LAT in T cells). The principal downstream target of Tec kinases is PLCγ.[23,24]

Adaptor proteins are noncatalytic and act as docking sites for other proteins via SH2 and SH3 domains. Linker for activation of T cells (LAT) is a transmembrane protein, whereas SH2-domain–containing leukocyte protein-76 (SLP-76) and BLNK are cytoplasmic. In their absence, activation of Src and Syk kinases fail to stimulate the Ras pathway and calcium flux induced by PLCγ.[25]

### PI3K/Akt Pathway

The PI3K family is divided into three classes on the basis of structure, regulation, and lipid substrate specificity. The focus of this discussion will be class I because it controls the Akt/mammalian target of rapamycin (mTOR) pathway which is involved in proliferation, differentiation, motility, and intra-cellular trafficking (see Figure 27-4).[26] Class I PI3Ks are composed of four heterodimeric proteins, including a catalytic (p110) and a regulatory (p85) subunit, and generate $PIP_3$ upon activation. The group is further divided into subclasses on the basis of the regulatory subunit they bind. Class IA is composed of p110 α, β, and δ catalytic subunits, which bind isoforms of p85, and are activated by tyrosine kinase–associated receptors. Phosphorylation of different ITAMs causes recruitment of PI3K through the SH2 domain and, eventually, generation of $PIP_3$ from $PIP_2$.[27] Akt is a serine/threonine kinase that is recruited to the plasma membrane through its PH domain and binds $PIP_3$. Akt is activated by phosphorylation by phosphoinositide-dependent kinase 1 (PDK-1) and mTOR complex 2. Active Akt phosphorylates a number of targets such as FOXO1, 3A and 4, GSK3α/β, RAF1, TSC2, and PRAS40 (both of which are then inhibited, allowing mTOR 1 function), IKKα (leading to activation of NF-κB), p21CIP1, BAD, or caspase 9.

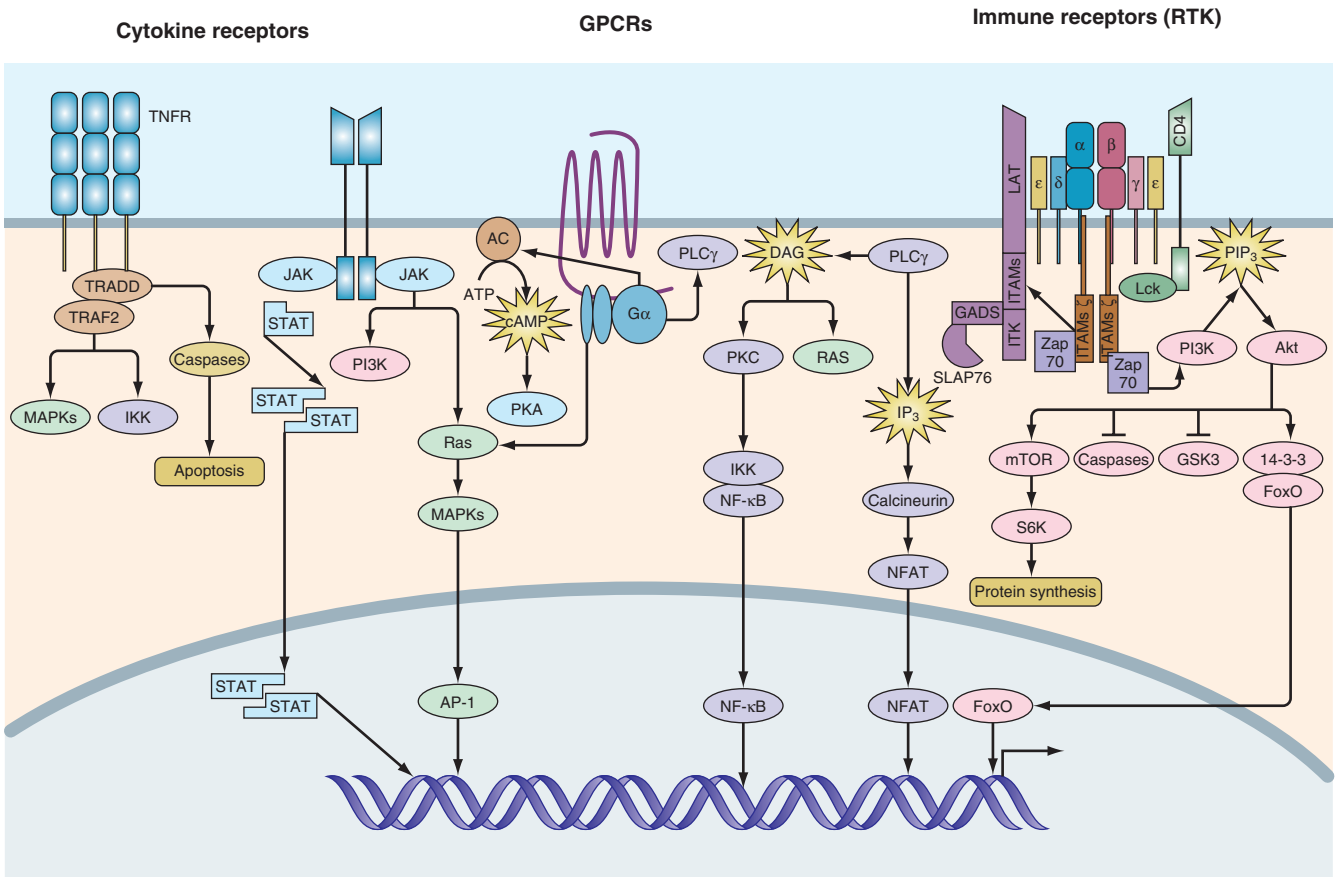

**Figure 27-4** Schematic depicting signaling pathways through cytokine receptors, G protein–coupled receptors (GPCRs) and immune receptors. AC, Adenyl cyclase; AP-1, activator protein-1; GADS, growth factor receptor-bound protein-2-related adaptor protein-2; ITAM, immunoreceptor tyrosine activation motif; JAK, Janus kinase; LAT, linker for activation of T cells; MAPK, mitogen-activated protein kinase; NFAT, nuclear factor of activated T cells; PI3K, phosphatidyl inositol-3-OH kinase; $PIP_3$, phosphatidylinositol-3,4,5-triphosphate; PKA, protein kinase A; PLC, phospholipase C; SLAP, Src-like adaptor protein; STAT, signal transducer and activator of transcription; TNFR, tumor necrosis factor receptor; TRAF, TNFR-associated factor; TRADD, TNFR-associated death domain.

## Phospholipase C Signaling: Calcium Flux and Protein Kinase C Activation

Activated PLC leads to generation of $IP_3$ and DAG from $PIP_2$. $IP_3$ is a soluble second messenger, which leads to release of stored $Ca^{2+}$ into the cytoplasm. This second messenger activates calmodulin and other $Ca^{2+}$-binding proteins. Calmodulin activates Ras/MAPK via indirect activation of Ras, or directly through activation of Raf-1.[28] In addition, calmodulin activates the serine/threonine phosphatase calcineurin, which dephosphorylates nuclear factor of activated T cells (NFAT). This exposes a nuclear localization signal (NLS) leading to nuclear import and transcription regulation.[29] On the other hand, DAG acts as a second messenger to stimulate PKC. These proteins are also related to the control of NF-κB (via phosphorylation of IKK) and activator protein (AP)-1 transcription factors.[30]

## MAP Kinase Pathway

A wide range of extra-cellular signals, including cytokines, stress, and growth factors, can activate a series of MAP kinases to ultimately regulate gene expression, and diverse cellular processes, including growth, proliferation, survival, and inflammatory immune responses. The MAPK signal cascades involve three tiers of activation (Figure 27-5). The first level of activation is the MAP kinase kinase kinase (MAPKKK or MAP3K), which includes activated Raf, apoptosis signal-regulating kinase (ASK)1, MEKK1-4, MLK, and TGF-β–associated kinase (TAK)1. MAPKKK phosphorylates and activates the next tier MAPKK, examples of which are MEK1/2, and the MKKs. MAPKK then phosphorylates the third tier of MAPK molecules, which include three families, namely, the extra-cellular signal-regulated kinases (ERK1/2), c-Jun N-terminal kinase (JNK), and p38 (α, β, γ, and δ), the latter two of which are stress-activated MAPKs. Finally, ERK, JNK, and p38 activate transcription factors, which include Ets, Elk-1, c-Myc activating transcription factor (ATF)2, p53, CREB, NF-κB, and AP-1. Activation of transcription factors may occur through direct phosphorylation or via modulation of ribosomal S6 kinase activity in the case of CREB, and via IKK in the case of NF-κB. JNK also regulates activity of non-transcription factors, such as the apoptosis-related Bcl-2 molecules.

Distinct signals activate the three families of MAPKs (although there can be considerable cross-talk)—ERK1/2, p38, and JNK. ERK1 and 2 are serine/threonine kinases that are components of the Ras-Raf-MEK-ERK cascade of the

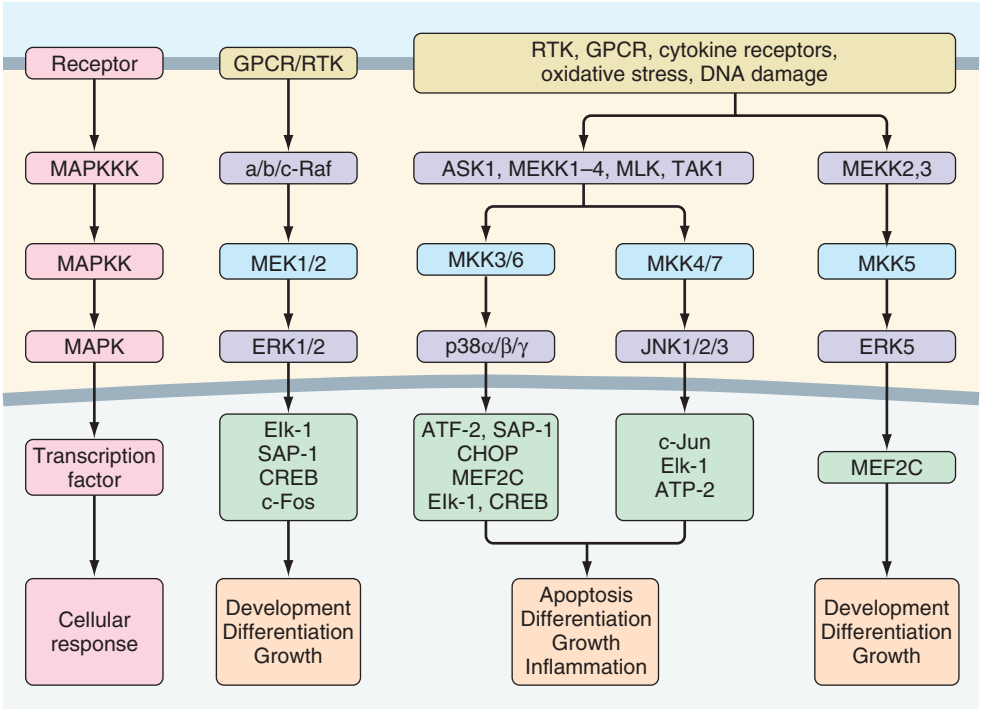

**Figure 27-5** Mitogen-activated protein kinase pathway (MAPK). A general schematic of the MAPK signaling pathway is shown on the left. On the right are specific receptors and three tiers in the MAPK cascades. Transcription factors and cellular responses activated by the different pathways are indicated. ASK, Apoptosis signal-regulating kinase; ATF2, activating transcription factor 2; C/EBP, CCAAT enhancer binding protein; CHOP, C/EBP homologous protein; CREB, cyclic adenosine monophosphate (AMP) response element–binding protein; ERK, extra-cellular signal-regulated kinase; GPCR, G protein–coupled receptor; JNK, c-Jun N-terminal kinase; MEF2C, myocyte-enhancer factor 2C; MLK, mixed lineage kinases; RTK, receptor tyrosine kinase; SAPK, stress-activated protein kinase; TAK, TGF-β–associated kinase.

MAPK pathways.[31] Whereas Raf and MEK kinases have limited substrate specificity, ERK1/2 phosphorylate and activate a vast number of cellular targets, including a large number of transcription factors. ERK1/2 are activated by a variety of cellular stimuli, including bradykinin, epidermal growth factor, FGF, insulin IGF1, PDGF, cytokines, and osmotic stress. Activation of this pathway regulates cell adhesion, migration, survival, proliferation, and differentiation. The p38 α and β isoforms are ubiquitous in their distribution; the γ isoform is mainly expressed in skeletal muscle; and the δ isoform is expressed in the testes, pancreas, and the small intestine. p38 MAPK is activated via pro-inflammatory cytokines and lipopolysaccharide (LPS). The p38 MAPK is critically important for the production of IL-1, TNF, and IL-6 pro-inflammatory cytokines. The JNK proteins are encoded by *JNK1*, *JNK2*, and *JNK3* genes, and alternative splicing results in additional isoforms and complexity. JNK1 and JNK2 are ubiquitous in their tissue distribution, whereas JNK3 is expressed mostly in the brain, heart, and testis. Pro-inflammatory cytokines, such as IL-1 and TNF, and UV radiation lead to JNK phosphorylation. The JNKs are involved in modulation of the extra-cellular matrix by regulating production of metalloproteinases.[32] A specific subgroup of protein tyrosine phosphatases that inactivate the MAPKs are called *MAP kinase phosphatases* (MKPs) and include MKP1, 3, 5, and 7, which can inactivate JNK and provide a means to regulate MAPK activity.

Therefore the MAPKs integrate signals from different receptors to regulate transcription factors to control a variety of overlapping genes and to ultimately regulate cellular survival, proliferation, and differentiation under physiologic and pathologic conditions.[33-35]

## Co-stimulatory Receptors

T cell activation requires two signals, one mediated through the T cell receptor and a second signal called *co-stimulation*. This signal is provided by a family of receptor-ligand molecules that mediate interactions between T cells and antigen-presenting cells. The B7/CD28 is one of the most well-studied pathways of costimulation. B7-1 and B7-2 are expressed by APCs and bind CD28 on T cells. This interaction triggers downstream signaling to amplify the primary signal and initiate effector responses. CD28 is phosphorylated by Lck and activates the PLCγ and PI3K/Akt pathways. An important consequence of this signaling pathway is to enhance mRNA stability of IL-2, which is responsible for the dramatic increase in IL-2 secretion. Cytotoxic T lymphocyte antigen (CTLA)4 is closely related to CD28 in structure, can bind to B7 molecules but with much higher avidity, and curbs the activation and proliferation of T cells.[36] In addition to the B7-CD28 pairing, other co-stimulatory molecules include the inducible co-stimulator (ICOS), which is induced on activated T cells and interacts with B7-H2/ICOSL on activated dendritic cells, monocytes, and B cells. Another class of co-stimulatory molecules is the signaling lymphocyte activation molecule (SLAM) family, a subtype of the immunoglobulin superfamily consisting of nine transmembrane proteins. SLAMs are important for multiple cell types, including T, B, and NK cells, and mediate

their effects via homophilic and heterophilic interactions. The SLAM proteins bear a tyrosine-based switch motif through which they bind SH2-bearing proteins SLAM-associated protein (SAP) and EAT2 with high affinity.[37]

Once activated, T cells express other co-stimulatory molecules, such as CD40L and the programmed cell death (PD)1 receptor. CD40L interacts with CD40 on APCs, and this induces signals, which play an important role in effector functions, such as activation of B cells, to produce antibodies. A co-stimulatory inhibitory pathway involves PD1 on T cells binding to B7-H1/PDL1 and B7-DC/PDL2 expressed on APCs.[38] PD1 belongs to the immunoglobulin superfamily, and its intra-cellular domain bears an immunoreceptor tyrosine-based inhibitory motif (ITIM) and an immunoreceptor tyrosine-based switch motif (ITSM). The tyrosine in the ITSM binds to the phosphatases SHP1 and SHP2, which act to inhibit the PI3K/Akt pathway. PD1 signaling inhibits induction of the antiapoptosis molecule BcL-xL and transcription factors such as T-bet, GATA-3, and Eomes, which are important for T cell differentiation.

Thus co-stimulatory signals not only activate cells to promote proliferation and effector functions required in the immune response but also are inhibitory to curb excessive activation and are important for tolerance induction.

### Adhesion Molecules

A variety of cellular functions, including lymphocyte activation, migration, and cell-cell interaction, involve adhesion molecules. These include selectins, integrins, and immunoglobulin superfamily molecules. L-selectin (CD62L) is important for lymphocyte homing to lymphoid tissues. Activated lymphocytes downregulate L-selectin and upregulate other adhesion/migratory molecules, such as CD44, a transmembrane protein, which recognizes hyaluronic acid and is critical for migration into peripheral sites of inflammation. CD44 lacks intrinsic kinase activity, but the cytoplasmic domain associates with Src family kinases Lck and Fyn. In addition, the cytoplasmic tail binds to the phosphorylated ezrin/radixin/moesin (pERM) proteins, which cross-link actin cytoskeleton proteins to CD44.[39] CD44 signaling also activates PI3K/Akt cell survival pathways.[40]

Integrins are heterodimeric cell surface proteins that provide interactions with other cells and the extra-cellular matrix, allowing for migration to effector sites. Various chemokines can activate integrins to mediate migration into lymphoid or nonlymphoid tissues. T lymphocyte integrins include leukocyte function-associated antigen (LFA)-1, LPAM-1, and very late activation antigen (VLA)-4, which bind immunoglobulin superfamily members ICAM-1, MAdCAM-1, and VCAM-1, respectively. Integrin activation results in inside-out signaling, which regulates the affinity of the integrin receptor to the extra-cellular ligands. Elements of this signaling pathway include the small GTPase RAP1 and its GEFs talin and kindlin3.[41-43]

## INNATE RECEPTOR SIGNALING

TLRs and nucleotide-binding oligomerization like receptors (NLRs) constitute the major pathogen sensors of innate immunity and work in a cell autonomous fashion to initiate anti-microbial responses, including inflammation and apoptosis (Figure 27-6). The major downstream effect of the cascades initiated by pathogen-associated molecular pattern (PAMP) recognition is IRF transcriptional activation of IFN genes that mediate inflammation and tissue repair. PAMPs are detected in endosomes and on the surface of cells by a variety of TLRs. These receptors have leucine-rich repeat domains to detect ligands, a single-pass membrane domain, and an intra-cellular Toll–interleukin-1 receptor (TIR) motif for downstream signaling. Their activities are most relevant in macrophages, monocytes, and dendritic cells.

TLR1, 2, 4, and 6 recognize varieties of endotoxin lipopolysaccharides from gram-negative bacteria, whereas TLR3, 7, 8, and 9 respond to nucleic acids that may also derive from viruses. TLR11 detects profilin protein, and the ligand for TLR10 remains uncharacterized. Response to ligand binding includes dimerization of receptors, which promotes docking of a variety of adaptor proteins, including myeloid differentiation factor (MyD)88, TIR-domain–containing adaptor protein-inducing IFN-β (TRIF), TIR-associated protein (TIRAP), and TRIF-related adaptor molecule (TRAM). A common downstream target of these cascades is NF-κB, which stimulates the transcription of inflammatory cytokines and IFN.

NLRs detect cytosolic PAMPs and endogenous inflammatory signals. Common motifs in these receptors include the nucleotide-binding oligomerization domain (NOD) and leucine-rich repeat (LRR). There are more than 20 versions of these receptors in mammals. The best-characterized is NOD1/CARD4 and NOD2/CARD15. NOD1 senses meso-diaminopimelic acid, found in gram-negative strains, whereas the NOD2 ligand is muramyl dipeptide, present in all bacteria.

A common downstream effect of pathogen detection is generation and release of IFNs. These glycoproteins are divided into three classes on the basis of the receptors that they activate. Type I IFNs bind the IFNA receptor (IFNAR), and this group includes IFN-α, IFN-β, IFN-ε, IFN-κ, and IFN-ω. IFN-γ is the sole member of type II in humans, and it binds IFNGR. Type III IFNs activate a receptor complex consisting of IL-10R2 and IFNLR1, and these are IL-29, IL-28A, and IL-28B. Activation stimulates JAK-STAT signal cascades and transcriptional changes made in cooperation with IRF proteins. The expression of so-called *interferon signature genes* (ISG) promotes anti-viral activities, increased MHC presentation, and apoptosis.

## INTRA-CELLULAR RECEPTOR SIGNALING

Steroid hormones synthesized from cholesterol in the adrenals and gonads, and vitamin D from dietary sources or produced by photochemistry in the skin, exert direct effects on gene expression via interaction with nuclear receptors. Because they are lipid soluble, these hormones can diffuse through plasma membranes to the nucleus to interact with receptors that directly modulate transcription, making them potent and common drug targets. In addition to endogenous molecules, many xenobiotics, such as endocrine disruptors, modulate these receptors. Almost half of the roughly 50 mammalian nuclear receptors have poorly characterized or multiple low-affinity ligands and are therefore known as *orphan receptors*.

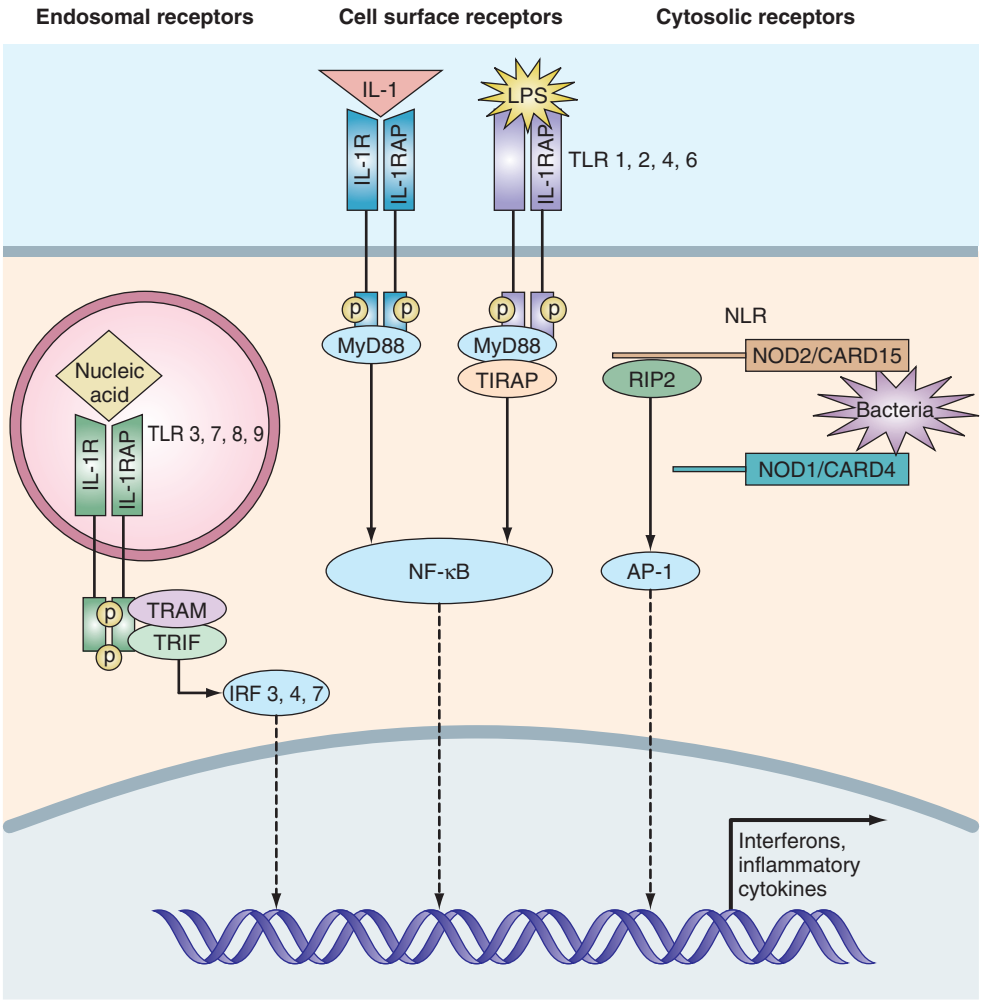

**Figure 27-6** Schematic depicting signaling through endosomal receptors, cell surface Toll-like receptors (TLRs) and cytosolic nucleotide binding oligomerization domain (NOD)-like receptors (NLRs). AP-1, Activator protein-1; CARD, caspase recruitment domain; IL-1RAP, IL-1 receptor accessory protein; IRF, interferon regulatory factor; LPS, lipopolysaccharide; MyD88, myeloid differentiation factor 88; NF-κB, nuclear factor-κB; TIRAP, Tir-domain–containing adaptor protein; TRAM, TRIF-related adaptor molecule; TRIF, Tir-domain–containing adaptor-inducing interferon-β.

Nuclear hormone receptors are broadly divided into two classes. Type I are retained in the cytoplasm until ligand binding drives a conformational change that releases binding partners, such as heat shock proteins, after which they translocate to the nucleus. Examples include the glucocorticoid, androgen, and estrogen receptors. Glucocorticoid agonists, such as dexamethasone and prednisolone, are important immunosuppressants. Activation not only drives gene expression changes following nuclear translocation but also transrepression of pro-inflammatory transcriptional complexes, such as AP-1 and NF-κB.

Another type I nuclear receptor of importance in immune signaling is the RAR-related orphan receptor gamma (RORγ). Derived from the *RORC* gene, mRNA for this protein is detectable in a variety of tissues, but its physiologic role is largely restricted to the RORγt isoform, critical for the development and maintenance of Th17 cells. This T helper is the primary source of pro-inflammatory IL-17, which makes RORγt a target for novel drug antagonists.[44]

Type II nuclear receptors generally reside on deoxyribonucleic acid and are inhibited by co-repressor proteins until ligand detection. Examples include thyroid hormone receptor (TR), retinoic acid receptor (RAR), and vitamin D receptor (VDR). They act as heterodimers in conjunction with cor-receptors, the most common of which is the retinoid X receptor (RXR). Although its major action is to regulate calcium absorption in the intestine and bone remodeling, vitamin D has increasingly been recognized as an immune modulator. Macrophages within granulomas convert vitamin D into its active form as part of an innate immune regulatory cascade.[45] Activated monocytes also generate this metabolite, and its effects are potentiated by IFNγ. In contrast, IL-4 generated by Th2, attenuates vitamin D effects, perhaps by stimulating its degradation.

## CONCLUSION

Discovery of these signaling pathways has provided valuable insights into immune pathogenesis of autoimmune and immunodeficiency diseases. Many receptors and/or signaling pathways are potential therapeutic targets for rheumatologic diseases. Because many of the signaling pathways and molecules are often widely expressed, carefully balancing risk and benefit of perturbing them will be a critical component of a drug development program.

CHAPTER 28

# Immunologic Repercussions of Cell Death

Helen M. Beere • Douglas R. Green

**KEY POINTS**

- **Apoptosis is a form of cell death induced by multiple stimuli and mediated by the activity of a group of cysteine proteases known as caspases. This type of cell death is characterized by the degradation of nuclear DNA and is generally non-inflammatory.**
- **Apoptosis and caspase activation can be triggered extracellularly by engagement of death receptors or intrinsically by mitochondrial damage and release of cytochrome-*c* and second mitochondrial-derived activator of caspase (SMAC)/DIABLO that function to activate caspases at the apoptosome.**
- **The B cell lymphoma 2 (BCL-2) family includes both pro- and anti-apoptotic proteins that control cell death by regulating the mitochondrial outer membrane potential.**
- **Necrosis and necroptosis are death processes that involve swelling of cells and rupture of the plasma membrane, resulting in inflammation.**
- **Necroptosis is a specialized form of necrosis that is initiated by death ligands and regulated by signaling pathways that are also important for the regulation of apoptosis.**
- **NOD-like receptor molecules act as cell stress sensors to trigger inflammasome assembly and activation of caspase-1 to mediate the processing and secretion of the pro-inflammatory cytokines IL-1β and IL-18.**
- **Autophagy is a normal cellular response to nutrient deprivation that is characterized by the degradation and recycling of cellular components.**

Cells are induced to die in response to a variety of stressors, signaling cues, and damaging events of both intra- and extra-cellular origin. Just as there are multiple types of death-inducing triggers, there too are several distinct cell death pathways, each of which is characterized by specific phenotypic and molecular features. Effective and efficient deletion of a damaged or dysfunctional cell necessitates engagement of self-destruction by different types of stress, be it DNA damage, metabolic disruption, or infection. But why evolve the capacity to eliminate cells by several different pathways, each with a unique phenotypic and molecular fingerprint? Once a cell is destined to die, why does it matter how the cell engages this death?

The answer to that question has proven more interesting than one might have predicted. As it turns out, not all cell deaths are created equal—some pathways are more equal than others, at least from the perspective of immune function. A dead or dying cell can impart signals to its neighboring cells, and these signaling events in turn determine critical physiologic responses essential for host survival. It is the type of cell death that occurs and the pathway by which a cell dies that determine the nature and identity of those signals, and these specific signaling events ultimately determine whether that cell death process is non-inflammatory or pro-inflammatory—or even in some cases actively suppresses inflammation. In this review, we will introduce several different types of cell death and discuss the defining features of each. The impact of these cell death pathways on immune function will be discussed in the context of disease pathologies associated with aberrant immune regulation and defects in cell death pathways.

## TYPES OF CELL DEATH

### Apoptosis

Apoptotic cell death or apoptosis (type I cell death) is perhaps the best characterized of the cell death pathways. The most prominent phenotypic characteristics of apoptotic cell death include perturbation and blebbing of the plasma membrane from which small membrane-bound vesicles, so-called "apoptotic bodies," are released. The plasma membrane maintains its integrity but undergoes lipid reorganization and "scrambling" to externalize phospholipids on the cell surface. As we will see, this event is particularly important with regard to how apoptotic cells are detected by the immune system. Within a cell dying by apoptosis, chromatin condenses and internucleosomal DNA cleavage generates the hallmark DNA "ladder" when separated on an agarose gel. The dying cell then begins to shrink, and if it is adherent, it detaches from neighboring cells and surrounding stroma and matrix.

The phenotypic changes associated with apoptotic cell death are mediated by the collective activities of a family of cysteine proteases, the caspases. It is the enzymatic activity of these ordinarily inactive zymogens that mediate, coordinate, and execute the apoptotic demise of the cell. As

such, caspase activation represents one of the most universal and informative descriptive biochemical features of apoptotic cell death. Of course it is not that simple—several different caspases exist, each of which is activated and regulated by different signaling pathways so that apoptotic cell death can be initiated in response to multiple types of damage or stress.

Once caspases have cleaved their target substrates, the now apoptotic cell is rapidly removed from the body via phagocytosis. Therefore, in contrast to other types of cell death, apoptosis generally, but not always, fails to evoke an inflammatory response. Even so, the term *immunologically silent*, which is often used to describe apoptosis, is somewhat misleading because an apoptotic cell, even when engulfed by a phagocyte, remains a source of signals that regulate components of immune function.

## Necrosis—Classical or Noncanonical?

Necrosis (type III cell death) is probably familiar as a nonprogrammed, disordered type of death that is characterized by swelling of both the cell and its intra-cellular organelles, rupture of the plasma membrane, and release of intracellular contents. Such death can be triggered by stresses such as altered tonicity, heat, or physical trauma and by intra-cellular events such as $Ca^{2+}$ efflux or a rapid decrease in adenosine triphosphate (ATP) levels. Other forms of necrosis, termed *necroptosis* or *programmed necrosis*, are also characterized by rupture of the plasma membrane but are fundamentally distinct from "classical" necrosis in that they are mediated by specific signaling events.[1,2] Cellular rupture, irrespective of its association with "classical" or programmed necrosis, releases numerous immune activators or danger-associated molecular patterns (DAMPs) into the immediate extra-cellular environment. Necrosis is therefore typically immunologically reactive because it generates a potent inflammatory response.

Several of the features that we typically associate with apoptosis can also be detected in cells undergoing necrotic death, including external exposure of phosphatidyl-serine, chromatin condensation, and their uptake by phagocytic cells of the immune system. The requirement for caspase activity is generally used to discriminate apoptosis from necrosis. However, not only are caspases dispensable for necrotic cell death, but programmed necrosis may actually require that their activity be inhibited.

Programmed necrosis can be induced by death receptors of the tumor necrosis factor (TNF) superfamily, members of the immune sensing Toll-like receptors (TLRs), and as part of the interferon (IFN) response. Accordingly, a close and in some cases overlapping functional relationship between signaling components of the immune system and those of programmed necroptosis is emerging. Furthermore, several components of the upstream death receptor signaling machinery are common to both programmed necrosis and apoptosis. How do we reconcile the apparent contradiction of common upstream signaling components with divergent biologic outcome? The answer is the selective activities of specialized death pathway–specific adapters that are able to integrate multiple signaling events to engage the effector molecules appropriate to the death pathway. In the case of programmed necrosis, the critical effector molecules appear to be receptor-interacting protein kinase 3 (RIPK3) and its substrate, mixed lineage kinase domain-like (MLKL). The precise mechanism underlying MLKL function to induce cell lysis remains incompletely understood, although several possibilities have been proposed.

## Pyroptosis

Pyroptosis, which is also a form of regulated necrosis, is a lytic type of cell death inherently associated with inflammation. It is mediated by the catalytic activity of the hence-named "inflammatory caspases" that include caspase-1 and, under some circumstances, caspase-5 (and caspase-11 in rodents).[3]

Beyond the defined requirement for caspase-1 activity to induce pyroptosis, how its downstream substrates mediate this type of cell death remains poorly defined. What we do know is that the morphologic characteristics of pyroptosis include rupture of the cell membrane and release of its intra-cellular contents into the immediate cellular milieu. This event provides a localized pool of potential pro-inflammatory molecules that include both direct activators of immune cells, such as cytokines and chemokines, as well as other signaling molecules or so-called "danger signals" able to trigger the production of inflammatory molecules from a variety of cell types. Rupture of a cell dying by pyroptosis is preceded by a marked increase in cell size that has been attributed to a caspase-1–dependent formation of membrane pores. It is the consequent disruption of ionic gradients across the cell membrane and an increase in osmotic pressure that causes water influx, cell swelling, and, ultimately, membrane rupture. Pyroptosis is also associated with DNA cleavage and nuclear condensation, although, in contrast to apoptosis, nuclear integrity is maintained. Although it is a caspase-1–dependent process, the identity of the nuclease responsible for DNA cleavage during pyroptosis remains unknown.

## Autophagy

Autophagy is a catabolic process of self-digestion in which components of the cell are enclosed within a double membrane to form an autophagosome that is then targeted to lysosomes for degradation. Autophagy is generally considered important for the maintenance of cell survival by providing energy and metabolites during times of starvation and for the removal of damaged organelles and long-lived proteins. It is also suggested that autophagy may engage cell death (type II cell death), particularly under conditions in which autophagy is enforced. However, the lack of stringent experimental discrimination between autophagy-induced cell death and autophagy arising as a consequence of cell death has proved to be a rich source of controversy. In an effort to formally determine if autophagic cell death is a bona fide type of cell death, a strict definition has been proposed—that the term *autophagic cell death* must only be applied from a functional perspective and only to scenarios in which cell death can be inhibited by the suppression of key regulators of autophagy. Nevertheless, our understanding of autophagic cell death is extremely limited, with very little insight into the physiologic conditions under which it is engaged.

## MOLECULAR MECHANISMS OF CELL DEATH

### Apoptosis

Apoptotic cell death is executed by one or more caspases, a family of cysteine proteases with selectivity for aspartate (Asp/D) residues, that cleave their target substrates after tetrapeptide sequences containing aspartic acid at the P1 position—for example, DEVD.[4] All caspases, although synthesized as inactive monomeric zymogens, require dimerization, in addition to other events, to acquire catalytic competence. The basic structure of the inactive procaspase comprises an N-terminal prodomain and a C-terminal protease domain, consisting of a large and a small subunit and the catalytic cysteine residue.

Caspases are broadly categorized according to their general function. The executioner caspases—caspase-3, -6, and -7—are the "do-ers"; that is, they are responsible for the cleavage of specific downstream targets to effect cellular destruction and clearance of the dead cell. In contrast, the initiator caspases, including caspase-8 and -9, provide the molecular "ignition" to initiate the proteolytic cascade and facilitate executioner function. Initiator caspases also include the so-called inflammatory caspases, caspase-1 and -5/11, and although they too initiate apical events to facilitate multiple downstream signaling events, their physiologic role is largely involved in immune regulation. However, emerging findings also implicate several roles in cell death. Caspase-2, despite displaying significant sequence homology to caspases found in primitive organisms, remains somewhat of a mystery. Although the molecular mechanism for its activation has been well characterized, the precise physiologic role for caspase-2 and the identity of its critical target substrates remain to be determined.

### Caspase Substrates of Note

Numerous caspase substrates have been identified, although only relatively few have been assigned functional significance. A critical caspase cleavage event is that mediated by the initiator caspases, which undergo autocleavage to stabilize the active dimer (in the case of caspase-2, -8, and -10) or destabilize it (in the case of caspase-9). Initiator caspases are also responsible for the necessary cleavage and activation of the executioner caspase-3 and -7 (another executioner caspase, caspase-6, is subsequently cleaved and activated by these executioner caspases). Once rendered enzymatically active, executioner caspases then cleave their target substrates to effect the phenotypic and biochemical characteristics of apoptosis. These target substrates include inhibitor of caspase-activated deoxyribonuclease (iCAD) to generate active CAD,[5,6] an endonuclease that cleaves between nucleosomes to generate the classical "DNA ladder"; poly-ADP-ribosyltransferase (PARP), an enzyme critical for DNA repair[7]; components of the cytoskeleton and matrix; and targets responsible for phosphatidylserine externalization to generate a critical extra-cellular signal used by phagocytic cells to remove dead cells.

Although the role of caspase-2 remains unclear, it can cleave BH3 interacting domain death agonist (BID)[8,9] to generate an active BH3-only protein that is able to induce mitochondrial outer membrane permeabilization (MOMP; discussed in more detail later). BID is also targeted by other caspases, including caspase-8[10] and -1.[11] Another substrate of caspase-2 is Golgi 160, although the precise role for this cleavage event is unclear.[12]

The inflammatory caspases, of which caspase-1 is the most well-characterized, directly target and cleave two pro-inflammatory cytokines, interleukin (IL)-1β and IL-18, to generate bioactive cytokines competent for secretion. Additional caspase-1 substrates include components of the actin cytoskeleton, the cellular inhibitor of apoptosis proteins (cIAPs), and metabolic enzymes, although the relevance of these cleavage events to caspase-1–dependent cell death remains poorly characterized. Unlike caspase-1, caspase-5/11 does not cleave the proforms of these cytokines, and the mechanism by which the latter causes cell death currently is not known.

### Caspase Regulation: Activation and Inhibition

In simple terms, there are two types of caspases, denoted "initiators" and "executioners," that require different mechanisms to achieve catalytic competence. Initiator or apical caspases have long prodomains and exist as inactive monomers that require dimerization to stabilize the catalytic site and to generate two catalytically active cysteines, one per monomer. This activation step is achieved by the assembly of oligomeric signaling complexes, comprising the apical caspase, specialized adapter proteins, and additional accessory regulatory proteins, and represents one example of the so-called "proximity" model of caspase activation. In contrast, the executioner caspases harbor minimal prodomains and exist as pre-formed inactive dimers that are rendered active via enzymatic cleavage of a DEVD site within an intradomain linker region between the large and small subunits. The resulting conformational change generates catalytically active caspase dimers. Therefore, dimerization of an apical caspase, enforced by recruitment to its specific activation complex, generates an active enzyme that, in turn, cleaves and activates downstream executioner caspases to mediate proteolysis of specific target substrates (as previously discussed) and, ultimately, cellular destruction.

### Caspase Inhibitors (Inhibitors of Apoptosis Proteins)

Although a critical event in engaging apoptosis, the irreversible consequences of caspase-mediated substrate cleavage might be, under some circumstances, undesirable for a cell. To that end, inhibitor of apoptosis proteins (IAPs), characterized by one or more copies of a motif called the baculovirus IAP repeat (BIR), can bind to and suppress active caspases, thereby inhibiting their destructive path.[13] These caspase inhibitors were first identified in viruses and function to maintain host cell survival, thereby ensuring sufficient time for viral replication.[14-16] Subsequently, based on BIR domain homology, a family of BIR-containing proteins was identified in vertebrates that includes X-linked inhibitor of apoptosis protein (XIAP),[17] c-IAP1, c-IAP2,[18] neuronal apoptosis inhibitory protein (NAIP),[19,20] and survivin.[21]

Although several members of this family have been implicated in the regulation of apoptosis, it is only XIAP that directly does so by interacting with active caspases to halt their activity.[17] XIAP is characterized by three BIR domains, with BIR3 and the adjacent RING domain mediating the inhibition of caspase-9 and BIR2 and the adjoining linker region suppressing the executioner caspase-3 and -7.[22] XIAP and other IAPs, including c-IAP1 and c-IAP2, can function as E3 ligases by virtue of their RING domain to promote ubiquitination and proteosomal degradation of their target protein substrates.[23] In this way, XIAP can also halt caspase activity by inducing protein degradation.

Evidence supporting a critical role for XIAP in the context of normal physiology is limited, particularly because XIAP-deficient mice have no obvious developmental defects.[24] However, in certain circumstances XIAP expression may be a critical determinant of cellular sensitivity to certain apoptotic pathways (discussed in more detail later).

## Caspase Recruitment Domains and Death Effector Domains—Activation Platforms of the Initiator Caspases

One of the critical events necessary for the activation of apical caspases is their recruitment to large protein complexes or signaling platforms. This step promotes dimerization and activation of the caspase. Complex specificity is determined by the identity of the specialized adapter molecules within these complexes and the reciprocal binding domain within the caspase itself. The prodomain of the initiator caspases contain one of two specialized binding domains, the caspase recruitment domain (CARD), present in caspase-1, -2, -4, -5 -9, -11, and -12, and the death effector domain (DED), found in caspase-8 and -10. The DED and CARD domains display no sequence homology, although structurally they are similar in that they form so-called "death folds." Additional protein domains discussed in the review, although not structural features of caspases themselves, are found in other molecules that participate in caspase activation. These include the death domain (DD) and pyrin (PYD) domains. It is these interaction domains that facilitate the recruitment of the caspases to their respective activation complexes (CARDs and DEDs) and/or are involved in accessory signaling events involved in their regulation (DDs and PYDs).

## The Inflammasome-Activation Platform for Procaspase-1 and -11

Caspase-1 is the prototypical human inflammatory caspase, although analogous roles have also been defined for caspase-5 (caspase-11 in rodents). As an initiator caspase, caspase-1 exists as an inactive monomer and requires dimerization to achieve catalytic competence. This is achieved by its CARD-dependent recruitment to a multiprotein complex, the "inflammasome," thereby triggering its activation and autocleavage. It appears that unlike the other caspases, caspase-1 is a much-desired binding partner, with multiple potential suitors or adapter proteins vying for its company. Presumably the functional diversity and availability of multiple adapter proteins ensures that upstream signaling events arising from multiple types of stresses can all converge on that one critical component of the pathway—the activation of caspase-1.

As previously discussed, caspase-1 is essential for the processing of the inactive proforms of IL-1β and IL-18 to generate active cytokines. Release of these bioactive cytokines from the cell occurs via a poorly defined noncanonical secretory pathway that also requires caspase-1 function. Because they are critical regulators of inflammatory responses to multiple stimuli of both self-derived and pathogenic origin, it is essential that biologically active IL-1β and IL-18 be readily available. To meet this need, adapter proteins must integrate signals arising from different origins and of diverse nature with the machinery required for caspase-1 activation.

Initiation of caspase-1–dependent IL-1β/IL-18 release can be triggered by numerous stimuli derived from both host and foreign sources, although is most often associated with components of pathogenic organisms. Triggers of caspase-1 activation are collectively termed DAMPs or "danger signals," and they function by engaging members of the NOD-like receptor (NLR) family. These intra-cellular sensors are collectively capable of responding to multiple stressors to engage the caspase-1–dependent processing of IL-1β/IL-18. Details of NLR-mediated caspase-1 activation and the activation of caspase-5/11 are discussed in more detail later.

## The PIDDosome Activation Platform for Procaspase-2

Caspase-2, despite being the most highly conserved caspase across all species, remains somewhat of a mystery in terms of its function, perhaps in part because only a very few of its target substrates have been identified.[25] Activation of caspase-2 is detectable in response to a range of different stresses including heat stress, metabolic disruption, and DNA damage, and although it can engage mitochondria-dependent apoptosis by cleaving BID, albeit poorly, it is not necessary, suggesting that the primary role of caspase-2 is not to induce cell death.

Although its precise role is unclear, the molecular determinants of caspase-2 activation have been characterized and, much like the other initiator caspases, it requires the regulated assembly of a large protein complex, termed the *PIDDosome*, to mediate caspase dimerization and activation.[26] The specific adapter protein involved in this process is receptor-interacting protein (RIP)-associated ICH-1/CED-3 homologous death protein with a death domain (RAIDD), a CARD-containing protein that interacts with the CARD domain of procaspase-2. RAIDD also contains a DD, which, by association with the DD of another accessory protein, P53-induced protein with a death domain (PIDD),[27] generates multimers of procaspase-9-RAIDD-PIDD. This process in turn leads to the dimerization and activation of procaspase-2, autocleavage, and stabilization of the active caspase.[25,28] What happens next remains a bit of a "black box," but disparate activities attributed to caspase-2 and its regulatory proteins, including a role in tumor suppression,[29,30] suggest that there is a lot more to the activity of this caspase that we have yet to understand.

## The Death-Inducing Signaling Complex Activation Platform for Procaspase-8

Activation of caspase-8 and -10 (not found in rodents) can arise from multiple signaling pathways emanating from a small group of so-called death receptors, a subset of the TNF receptor family, when they are ligated by their cognate death ligand, which are also TNF-like molecules. Depending on the precise identity of the accessory proteins in the activating signaling complex, procaspase-8 cleavage and/or activation can then participate in several biologic pathways. Nonetheless, a few key mediators are involved in the recruitment and activation of caspase-8 via the adapter domains, the DD, and the DEDs, common to the activation of these initiator caspases.

Constitutively trimerized death receptor is activated by trimers of death ligand to expose an intra-cellular DD that is then available for multiple homotypic DD-DD interactions with one of several adapter molecules that includes the Fas-associated protein with a death domain (FADD). This interaction triggers the exposure of the FADD DED domain and enables assembly of the mature signaling death-inducing signaling complex (DISC) by the recruitment of procaspase-8 or -10 via one of the two DED domains of these initiator caspases. This enforced dimerization enables formation of an active catalytic site that then promotes autocleavage and stabilization of an active caspase dimer, which then cleaves and activates the effector caspases 3 and 7—that is, unless procaspase-8 forms heterodimers with a catalytically inert homolog, FADD-homologous ICE/CED-3-like protese (FLICE)-like inhibitory protein (FLIP), which is a negative regulator of procaspase-8 activity. FLIP-procaspase-8 heterodimers, although lacking the ability to promote apoptosis, retain sufficient catalytic activity to inhibit an alternative form of cell death, necroptosis, that is discussed in more detail later.

## The Apoptosome-Activation Platform for Procaspase-9

Procaspase-9 is rendered catalytically active by its recruitment to a large protein complex called the apoptosome, comprising procaspase-9, apoptotic protease activating factor-1 (APAF-1), and additional regulatory proteins.[31,32] APAF-1 is a specialized adapter protein containing an N-terminal CARD domain and a C-terminal protein-binding domain consisting of multiple WD repeats. APAF-1, which is important for development,[33,34] is a cytosolic molecule that is triggered to undergo self-oligomerization by the binding of cytochrome-*c* once it is released from the mitochondrial intermembrane space.[32] Association with cytochrome-*c*, together with the binding and hydrolysis of deoxynucleotides (deoxyadenosine triphosphate [dATP]), induce the conformational changes in the APAF-1 molecule to unmask the C-terminal CARD domain. This process then enables the recruitment of procaspase-9 to the complex via homotypic CARD-CARD interactions[35] to facilitate the dimerization and generation of catalytically active caspase-9.[36] The mature caspase-9–activating complex or apoptosome consists of an APAF-1 septamer, with each APAF-1 molecule able to recruit and activate dimers of caspase-9. Once activated, caspase-9 cleaves and activates the executioner caspases 3, 6, and 7. Autocleavage of caspase-9 causes its release from APAF-1, and the caspase is now inactive. This action liberates APAF-1 to recruit additional procaspase-9, resulting in a "tick-over" of active caspase-9 until sufficient active executioner caspase is produced to propagate the apoptotic signal.

## Mitochondria and Apoptosis—Intrinsic Apoptosis

### Release of Intermitochondrial Regulators to Activate Caspases

Caspase-dependent apoptosis is broadly defined as two pathways that, for the most part, proceed independently of one another—the mitochondria-dependent "intrinsic" pathway and the "extrinsic" pathway that is mediated by death receptor/death ligand interaction (discussed in further detail later). The former pathway, which is dependent upon the initiator caspase-9, is characterized by permeabilization of the outer mitochondrial membrane to release cytochrome c, an intermembrane component of the electron transport chain, into the cytosolic space.[37-39] Once released, cytochrome-*c* binds to APAF-1 to facilitate assembly of the apoptosome and activation of procaspase-9 (previously described). Several additional proteins are also released that include second mitochondrial-derived activator of caspase (SMAC), also known as DIABLO; OMI/high temperature requirement A2 (HTRA2); and apoptosis-inducing factor (AIF).[40-42] SMAC and OMI participate indirectly in caspase activation through binding and antagonism of XIAP (discussed in more detail later).

## Mitochondrial Outer Membrane Permeabilization and Apoptosis

MOMP is a regulated process that permits the release of proteins critical for the induction and regulation of apoptosis.[38-41] Although the outer mitochondrial membrane is endowed with transporters, such as translocase of the inner membrane (TIM) protein complex,[40] that regulate the import and export of proteins, the release of mitochondrial proteins involved in cell death is mediated by an entirely independent mechanism that is engaged only in response to apoptotic stimuli. So how do the specific signals arising from multiple types of apoptosis-inducing stimuli and differing vastly in nature all culminate in disruption of the mitochondrial outer membrane to release cytochrome-*c*?

## Regulation of Mitochondrial Outer Membrane Permeabilization

MOMP is one of the primary features of the intrinsic apoptotic pathway and is positively and negatively regulated by the collective activity of the B cell lymphoma 2 (BCL-2) family of proteins (Figure 28-1; reviewed in references 43 and 44).[43,44] BCL-2 proteins are functionally categorized into those that promote and those that suppress cell death by directly or indirectly regulating MOMP according to specific structural features.[45] BCL-2 proteins are characterized by one or more 20 amino acid stretches of conserved residues corresponding to α-helical segments and constituting the

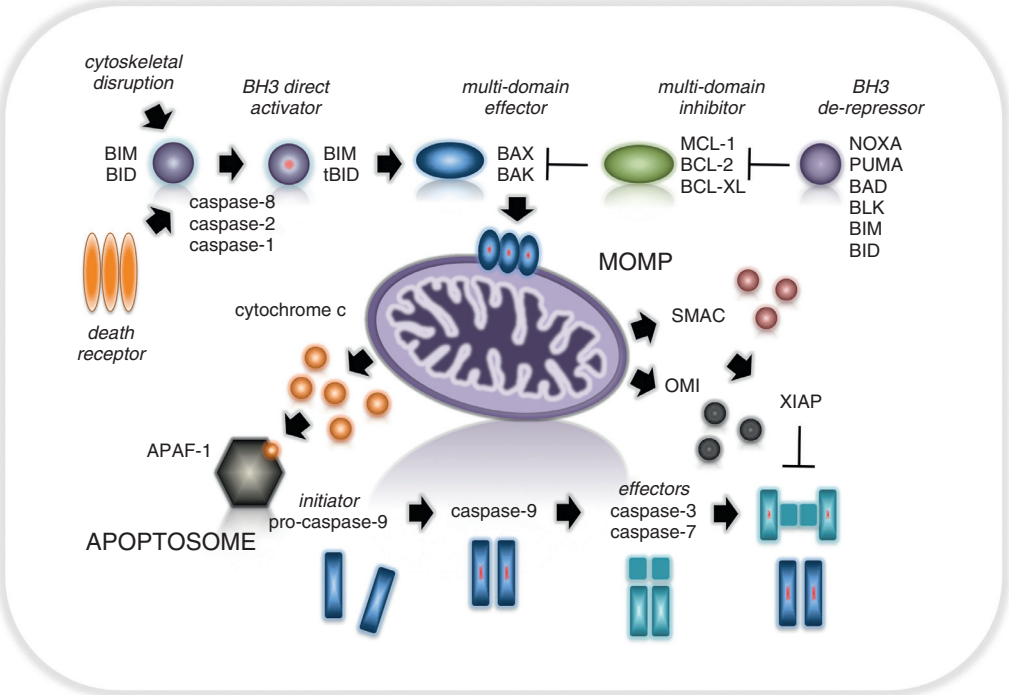

**Figure 28-1** B cell lymphoma 2 (BCL-2) protein-regulated mitochondrial outer membrane permeabilization (MOMP) is a critical event in the intrinsic apoptosis pathway. BCL-2 proteins regulate MOMP in response to a multitude of signals to engage the intrinsic apoptotic pathway. The multidomain proapoptotic effector molecules BAX and BAK undergo several modifications, including conformational change and oligomerization to induce MOMP. The multidomain anti-apoptotic BCL-2 proteins including BCL-2, BCL-$X_L$, and MCL-1 inhibit BAX/BAK–induced MOMP. The proapoptotic BH3-only effector proteins activate BAX and BAK either by direct activation (direct BH3 activators include BIM and BID) or indirectly by displacement of inhibitory anti-apoptotic BCL-2 proteins (de-repressor BH3 proteins include NOXA, PUMA, and BAD). BH3 proteins act as sensors to different types of stress and can be modified by several mechanisms. For example, BID is cleaved and activated by caspase-8 in response to death receptor–mediated signaling events, whereas BIM activation can be mediated by disruption of the cytoskeleton. MOMP permits the release of several intermembrane space proteins, including cytochrome-*c*, second mitochondrial-derived activator of caspase (SMAC), and OMI, all of which regulate the apoptotic pathway. Cytochrome-*c* binds to the adapter protein apoptotic protease activating factor-1 (APAF-1) to trigger the recruitment of inactive procaspase-9 monomers and assembly of the apoptosome complex. This action results in the self-cleavage of procaspase-9 to generate catalytically active caspase-9 dimers, which then cleave and activate the executioner caspase-3 and -7. X-linked inhibitor of apoptosis (XIAP), an E3 ligase, negatively regulates the activity of caspase-9, -7, and -3 either by blocking of the catalytic site or by promoting their ubiquitin-dependent degradation. SMAC and OMI bind to or cleave XIAP, respectively, to inhibit its activity and promote apoptosis. *(From Tait SW, Green DR: Mitochondrial regulation of cell death.* Cold Spring Harb Perspect Biol *5, 2013.)*

so-called BH (BCL-2 homology) domains, numbered 1 to 4 (BH1, -2, -3, and -4). Both the anti-apoptotic and effector BCL-2 proteins are characterized by multiple BH motifs, whereas, as the name suggests, BH3-only BCL-2 proteins are characterized by a single BH3 domain.

The proapoptotic multidomain effector proteins, BAX and BAK, directly permeabilize the outer mitochondrial membrane, whereas the anti-apoptotic family members, including BCL-2 itself, BCL-$X_L$, A1, BCL-B, BCL-w, and MCL-1, function primarily to prevent MOMP. The so-called proapoptotic BH3-only proteins, including BID, BIM, PUMA, NOXA, HRK, BIK, BMF, and BAD, also promote MOMP, but they do so indirectly, either by activating the BAX and BAK effectors or by inhibiting the anti-apoptotic BCL-2 proteins.[46]

Although BAX and BAK are the primary mediators of MOMP, the precise mechanism by which they achieve membrane permeabilization remains only partially understood. In their respective inactive states, monomeric BAX is found in the cytosol, whereas BAK resides on the outer mitochondrial membrane, anchored by its carboxy-terminal region. Conversion to their active state requires transient interaction with one or more of the BH3-only proteins to induce a change in their conformation, multimerization into large homo-oligomers, and, in the case of BAX, translocation to the outer mitochondrial membrane. The subsequent release of intermembrane space proteins clearly requires membrane permeabilization, but whether BAX and BAK oligomers achieve this effect directly, by membrane insertion and forming pores themselves, or indirectly, by triggering the formation of lipid pores, has yet to be resolved. Nonetheless, after permeabilization is achieved, cytochrome-*c*, SMAC (DIABLO), and OMI (HTRA2) are released from the mitochondrial intermembrane space into the cytosol to activate caspases and mediate apoptotic cell death.

A third BCL-2 family member, BOK, is also grouped with the effectors BAX and BAK because it too contains BH domains 1 to 3.[47] BOK can induce cell death when overexpressed,[48-50] but whether it functions to promote membrane permeabilization and MOMP has yet to be convincingly demonstrated. Neither the ablation of *Bok* expression nor its co-deletion with *Bax* or *Bak* revealed any overt developmental phenotype,[51] suggesting that if BOK does have a role in cell death, it is either minor or developmentally redundant. Interestingly, recent in vitro findings describe a

BAX/BAK-dependent prodeath function of BOK, resulting from its predominant localization at the endoplasmic reticulum (ER) and/or Golgi membranes.[31] However, the role of BOK remains somewhat of a mystery for now, although given the pace at which this field has advanced, it is likely only a matter of time before its physiologic role is revealed. Interestingly, *Bok*, unlike both *Bax* and *Bak*, is frequently deleted in cancers,[52] adding further intrigue to its as yet unknown functions.

Despite extensive structural and functional characterization of the BCL-2 proteins and overwhelming evidence that the anti-apoptotic BCL-2 proteins suppress BAK- and BAX-mediated MOMP, exactly how this process occurs remains obscure. What we do know is that the BCL-2 proteins interact with BAX and BAK to prevent their oligomerization. This interaction is mediated by the BH3 domain of BAX and BAK and a binding groove, common to all the anti-apoptotic proteins, composed of multiple α-helices containing BH domains 1 to 3. Because, under constitutive conditions, the BH3 domain of BAX and BAK is "buried" and therefore unavailable for binding, evidence indicates that insertion into the outer mitochondrial membrane is accompanied by a conformational change to reveal the BH3 domain in these proteins. Accordingly, exposure of the BH3 domain of BAK or BAX renders it competent for either self-oligomerization to induce MOMP or, alternatively, interaction with an anti-apoptotic molecule to inhibit it. Interestingly, BAX and BAK display selectivity for different anti-apoptotic proteins in that BAK preferentially interacts with BCL-$X_L$ and MCL-2, whereas BAX "prefers" to associate with BCL-2 and BCL-$X_L$ (and less so with MCL-1). Paradoxically, however, each of the three anti-apoptotic BCL-2 proteins is equally effective at suppressing apoptotic cell death driven by either BAX or BAK. Thus, although the model by which the anti-apoptotic proteins suppress the activity of BAX and BAK to inhibit MOMP is well substantiated, its applicability to both BAX and BAK and all anti-apoptotic BCL-2 proteins is limited. To fully understand the complexity of BAX and BAK regulation by the anti-apoptotic BCL-2 proteins, the activity of BH3 proteins also must be considered.

The proapoptotic BH3-only proteins serve as upstream sensors to integrate the signals arising from intra-cellular stresses to engage apoptosis via BAX and BAK. Although BAX and BAK act as the terminal effectors of MOMP and are negatively regulated by their direct interaction with the BCL-2 proteins, association between the BH3-only and anti-apoptotic BCL-2 proteins can also have an impact on BAX- and BAK-mediated MOMP. Sequestration of the anti-apoptotic BCL-2 proteins by the BH3-only proteins serves to neutralize their inhibitory activity and increase the likelihood of unimpeded BAX and BAK activation to induce MOMP. Importantly, under these conditions, the sensitivity of cells to BAK- and BAX-mediated apoptosis is ultimately determined by both the availability of a given BH3-only protein and its binding specificity for a particular anti-apoptotic protein.[53,54]

We have described how the activation of BAX and BAK can be inhibited by association with anti-apoptotic BCL-2 proteins and how they in turn can be neutralized by interaction with certain BH3-only proteins. How, then, are BAX and BAK, which we know to exist in a constitutively inert state, activated to exert their proapoptotic activities? The solution to this particular conundrum lies in the remarkable ability of certain of the BH3-only proteins to directly trigger BAX and BAK activation. This group of so-called "direct activators" remains somewhat exclusive, with only BID, BIM, and possibly PUMA thus far fulfilling membership requirements. Unlike interactions between anti-apoptotic BCL-2 proteins and proapoptotic multidomain effectors or the BH3 proteins, both of which can be isolated as hetero–BCL-2 protein complexes, activation of BAX or BAK by the direct activators is instead mediated by a transient "hit and run"–type interaction. Interaction between the BH3 activators and effector molecules elicits exposure of the BH3 domain of BAK or BAX, thereby rendering it available for homo-oligomerization, pore formation, and MOMP.

Although the exact mechanism by which BH3 proteins activate BAX and BAK remains a source of discussion, it would seem that the two models proposed are not necessarily mutually exclusive and in due course may prove to be equally valid, depending upon the circumstances.[55] The "neutralization" model argues that BH3-mediated disruption of interaction between a BCL-2 effector molecule and an anti-apoptotic BCL-2 protein both liberates BAX or BAK *and* renders it functionally competent to induce MOMP and apoptosis. The logical extension of this model is that whether a cell lives or dies is determined by the relative ratio of proapoptotic BCL-2 proteins to anti-apoptotic BCL-2 proteins. The alternate "de-repression" model also proposes that interaction between the BH3-only and anti-apoptotic BCL-2 proteins relieves BAX and BAK from the restraints of BCL-2–mediated inhibition. However, the model further suggests that the release of BAK and BAX is not synonymous with pore-forming activity. Instead, it proposes that once BH3-mediated disruption of interaction between BAX or BAK and anti-apoptotic Bcl-2 proteins has released the effector molecule, MOMP can only proceed *if* BAX or BAK is first rendered active by a "direct activator" such as BID or BIM.

Although these two models are not at odds with one another, the primary distinction between the two—that BH3 proteins displace active BAX or BAK from anti-apoptotic proteins versus the idea that both the displacement and activation of BAX and BAK by two different but complementary BH3-dependent mechanisms is required—is of significance in the context of the design of pharmacologic regulators of BCL-2 protein function.

Although it remains to be seen if, in addition to BID, BIM, and PUMA, other BH3 proteins might also harbor the ability to directly activate BAX and/or BAK, it is clear that most cannot. Interestingly, though, the identification of cytosolic p53 as a direct activator of multidomain BCL-2 effectors[56] raises the possibility of additional as yet unidentified non-BH3 proteins capable of directly activating BAX and BAK.

## Post-Translational Regulation of Bcl-2 Protein Function

BCL-2 proteins can also be regulated by several post-translational modifications. Post-translational modification of BCL-2 proteins serves as a general mechanism by which upstream signaling events arising from different types of

stress can selectively engage one or more downstream BCL-2 proteins to regulate cell death. Modifications include phosphorylation, ubiquitin-mediated degradation, protease-mediated cleavage, myristiolyation, and neddylation. Although the precise functional consequences of these modifications are not clear in most cases, a few exceptions exist.

BH3 proteins act as the upstream sensors of multiple types of stresses to then engage the downstream proapoptotic effector molecules, BAX and BAK. In many instances this effect is achieved by the stress-specific activation of kinases that in turn modify BH3 proteins via site-specific phosphorylation. Nutrient withdrawal and the consequent reduction of intra-cellular energy stores is a potent activator of cell death that, in many instances, is attributed to the proapoptotic activities of the BH3-only proteins BIM and BAD. At least in part, kinase-mediated phosphorylation of specific residues within these BH3-only proteins are critical for the integration of upstream signaling events associated with growth factor withdrawal and activation of downstream apoptotic effectors. Activation of AKT, a serine-threonine kinase, by growth factor receptors leads to the phosphorylation and cytosolic sequestration of the transcription factor FOXO3a by 14-3-3 proteins.[57] However, disruption of this signaling pathway under conditions of nutrient withdrawal permits translocation of FOXO3a to the nucleus, where it induces the transcription of a number of genes, including *Bcl2-like11 (Bcl2l11)*.[58] Phosphorylation of BIM at serine-69 by extra-cellular-signal regulated kinase (ERK), a mitogen-activated protein kinase (MAPK) activated in response to growth factors, promotes the proteosomal degradation of BIM to facilitate cellular survival.[59] In contrast, the phosphorylation of BIM by the MAPK, JNK, stabilizes the protein to facilitate cell death in a BAX-dependent manner.[60] Phosphorylation of BAD at residues Ser-112 and Ser-136 by AKT renders it inactive by promoting association with and sequestration by 14-3-3,[61] whereas the dephosphorylation of BAD in response to nutrient deprivation neutralizes its proapoptotic activity by triggering its interaction with BCL-$X_L$ or BCL-2.[62-64] Protein kinase A (PKA)-mediated phosphorylation of BAD at serine-112 also inhibits apoptosis by maintaining BAD in the cytosol, thereby inhibiting activation of BAK/BAX at the mitochondrial membrane.[65] Whereas BIM is a direct activator of BAX and BAK, BAD is a de-repressor protein that promotes apoptosis by neutralizing the anti-apoptotic BCL-2 proteins, BCL-2 and BCL-$X_L$.

Multiple phosphorylation and ubiquitylation events also contribute to the regulation of myeloid cell leukemia 1 (MCL-1) stability.[66] Disruption of AKT activity under conditions of nutrient withdrawal relieves the inhibition of the kinase, glycogen synthase kinase 3 (GSK3), which in turn is then able to phosphorylate MCL-1. This phosphorylation event promotes the degradation of MCL-1, thereby reducing its anti-apoptotic effects to facilitate apoptosis.[67] Also involved in the regulation of MCL-1 protein turnover is MCL-1 ubiquitin ligase E3 (MULE), which is somewhat unusual in that it harbors a BH3 domain. Interaction with MCL-1 via the BH3 domain of MULE limits its enzymatic activity, but once displaced by a proapoptotic BH3-only protein such as NOXA, it is then able to ubiquitlylate MCL-1, rendering it susceptible to degradation.[68] Other proteins that control the stability of MCL-1 include FBW-7,[69] a tumor suppressor frequently deleted in cancers, and the deubiquitinase USP9X,[70] which is expressed in many tumor types. The turnover of the anti-apoptotic proteins BCL-2 and BCL-$X_L$ are similarly subject to regulation by post-translational modification.[71,72] For example, ERK1/2-mediated modification of a serine residue (Ser-70) within the flexible loop between the BH3 and BH4 domains[73] or on serine-87 of BCL-2 both exacerbate its anti-apoptotic activity, at least in part, by maintaining protein stability.[74] Dephosphorylation by protein phosphatase 2A (PPA2) opposes this activity and neutralizes the anti-apoptotic activity of BCL-2.[75] In contrast, the anti-apoptotic activity of BCL-$X_L$ is disrupted by the deamidation of two asparagine residues in the unstructured loop between BH4 and BH1.[76]

Specific cleavage events can also contribute to the function of certain BCL-2 proteins. The BH3-only protein BID is unique among its BH3 relatives in that in its native state, its BH3 domain is buried within the tertiary structure of the molecule. Without exposure of this domain, BID cannot interact with other BCL-2 proteins and is therefore biologically inert. However, cleavage of a flexible linker within BID by one of several proteases, including caspase-8[77] and -2,[8] granzyme B,[78] lysosomal proteases (cathepsins),[79] and the calcium-activated protease, calpain,[80] generates an active cleavage product, tBID, rendering it able to associate with anti-apoptotic proteins or function as a direct activator of BAX and BAK. In this way, upstream cytosolic events leading to the activation of these proteases can engage mitochondria-dependent apoptosis by the direct cleavage and activation of the BH3 protein, BID. Calpain-mediated cleavage of BAX to enhance its pro-apoptotic activity has also been described,[81] although the physiologic significance of this event has yet to be fully delineated. Like BIM, active BID is capable of directly activating BAX and BAK.

Regulation of gene expression is also a mechanism by which the levels of BCL-2 proteins can be modulated to affect the overall susceptibility of cells to apoptosis. Multiple transcription factors have been implicated in the regulation of both pro- and anti-apoptotic *Bcl-2* gene expression, including p53, nuclear factor-κB (NF-κB), and FOXO3a. Several microRNAs (miRNAs), including miR-17-92, miR-15, and miR-16, have also been shown to specifically reduce the levels of *Bim* and *Bcl-2* RNAs, respectively. Several of the BCL-2 proteins exist as multiple splice variants, including BCL-$X_L$, BAX, and PUMA, although their specific roles are poorly defined. However, BIM, found in multiple isoforms, including $BIM_S$, $BIM_L$, and $BIM_{EL}$, appear to harbor differing proapoptotic potencies as a consequence of the presence or absence of a dynein light chain–binding region. Anoikis, which is apoptotic cell death arising from perturbation of the cytoskeleton and detachment of cells from the basement membrane, is mediated by BIM and another BH3 protein, BCL-2 modifying factor (BMF). BIM is anchored to the microtubule complex, whereas BMF is sequestered by the actin cytoskeleton, each by their respective dynein light chain–binding regions. Disruption of the cytoskeleton induces the release of BIM and BMF to promote MOMP and engage apoptosis.

## Alternative/Additional Roles of Bcl-2 Proteins

Our discussion of BCL-2 function has focused on their role in the regulation of cell death in the context of MOMP regulation. Although this role is critically important, it is becoming apparent that the collective activity of BCL-2 proteins is not restricted to the regulation of cell death but that it likely has a significant impact in several additional signaling pathways, including the regulation of mitochondrial dynamics,[82] the response to DNA damage,[83,84] metabolic bioenergetics,[85-87], $Ca^{2+}$ homeostasis,[88] ER function, and autophagy.[89]

## Is MOMP Really the End of It All?

MOMP is clearly a critical event in apoptotic cell death and is regulated by the collective activity of the BCL-2 protein family. However, the induction of MOMP is an equally important event for caspase-independent cell death (CICD), and as in apoptosis, it is dependent upon BCL-2 protein function. The engagement of cell death in the context of caspase inhibition can promote a type of cell death that is characterized by MOMP—so-called CICD. This type of cell death is perhaps most commonly observed during development and particularly under conditions in which certain pathways of caspase activation are inactivated, such as the *Apaf-1*–deficient model. In this case, cells die as a result of a bioenergetic catastrophe as mitochondrial function is lost upon MOMP. The release of intermembrane space proteins upon MOMP, including AIF, has also been proposed to participate in this form of cell death.

Although MOMP is generally considered the point at which the cell is irreversibly committed to cell death, specific circumstances exist in which this may not be the case. Tumor cells are able to circumvent the terminal consequences of MOMP by both inhibiting caspase activity and by preserving a small pool of intact mitochondria capable of regeneration and restoration of cellular bioenergetics. Suppression of caspase activity can be achieved via several means, including the harnessing of XIAP activity and by the downregulation of critical components of the apoptotic machinery by mechanisms such as epigenetic silencing and ubiquitin-mediated degradation. Therefore, MOMP does not always lead to cell death. However, this is the least likely consequence that is most often associated with a variety of disease pathologies and not normal cellular function, perhaps with the exception of postmitotic cells such as neurons.

## Death Receptor–Associated Signaling Events—Extrinsic Apoptosis

The so-called "extrinsic" pathway of apoptosis is initiated by the interaction of extra-cellular "death ligands" with their respective extra-cellular "death receptors" on the cell surface, in response to a variety of different types of stress and developmental signals. The obligate caspase for death ligand–mediated apoptosis is caspase-8, which, like other initiator caspases, exists as an inactive monomer and requires homodimerization to generate enzymatic activity. The death ligands and their receptors represent subsets of the TNF and TNF receptor (TNFR) superfamilies, respectively. The receptors include TNFR1, CD95 (also known as Fas or Apo-1), death receptor (DR) 3 (DR3), the TNF-related apoptosis-inducing ligand (TRAIL) receptors, TRAIL receptor 1 (or DR4), TRAIL receptor 2 (also known as DR5 in humans), and DR6. Their corresponding activating ligands are TNF itself, CD95 ligand (or FasL), and TRAIL, all of which engage apoptosis. Neither DR3 nor DR6 (the ligand for which remains unidentified) promotes apoptosis.

Both the DRs and their ligands exist as pre-formed trimers. Upon interaction of a DR with the appropriate ligand, a conformational change exposes a specialized protein-association domain in the receptor, the DD (mentioned previously). The unmasking of this DD then renders it available for interaction with one of several adapter proteins that contain DD.

Interaction between FASL (CD95 ligand) and its receptor FAS (CD95) reveals the intra-cellular DD-containing receptor region, with which FADD then interacts via its own DD. This interaction is accompanied by a conformational change in FADD to reveal a second specialized binding domain, the DED. Multimerization of the FAS-FADD complex is attributed to the ability of DDs to associate at three different interfaces and has been shown to be necessary for the subsequent recruitment and activation of caspase-8. Assembly of the mature signaling complex or CD95 DISC is completed by the recruitment of procaspase-8 via interaction between one of two DEDs in its prodomain and the DED of FADD. The consequent dimerization of procaspase-8 permits self-cleavage and stabilization of the active caspase, leading in turn to the proteolysis and activation of the effector caspase-3 and -7. DISC formation is an extremely efficient process that is negatively regulated by the dimerization of caspase-8 with its catalytically inactive homolog, FLIP. Although this interaction prevents the dimerization and cleavage of caspase-8, it does not completely inhibit its catalytic activity, which results in the cleavage of FLIP but, importantly, not the induction of apoptosis. Recently, studies have further characterized the complexity of binding between FADD, FLIP, and caspase-8, demonstrating it to be an important determinant of the type of cell death that proceeds, apoptosis or necroptosis (discussed in detail later).

TRAIL ligation to its receptor engages caspase-8 activation and subsequent apoptotic cell death in a similar manner to that described for FAS and its ligand FASL. Negative regulatory mechanisms for TRAIL-induced death are poorly characterized but likely, at least in part, involve FLIP-mediated events.

The signaling events elicited by activation of the TNFR1 are complex, subject to a variety of regulatory mechanisms, and lead to cellular survival, apoptosis, or programmed necrosis, depending upon the specific identity of the proteins recruited to the TNFR1 receptor-signaling complex, termed complex I, IIa, and IIb (Figure 28-2). TNFR1 activation can be mediated by one of two ligands, TNF itself or lymphotoxin, both of which trigger conformational changes within the intra-cellular domain of the receptor to expose the DD, as well as an additional binding site for an E3 ligase, TNF receptor–associated factor 2 (TRAF2). Subsequent recruitment of TNFR1-associated death domain (TRADD) to TNFR1 via their respective DD domains serves to both

stabilize the TRAF2-TNFR1 interaction and recruit RIPK1. Additional components of this so-called complex I include cIAP1, cIAP2,[90] and linear ubiquitin chain assembly complex (LUBAC), itself a complex consisting of HOIL-1, HOIP, and SHARPIN. Ubiquitination of components within this complex by one or more of the E3 ligases, TRAF2, cIAP1, cIAP2, and HOIL-1, are essential for the recruitment and activation of additional signaling proteins (Figure 28-2A). RIPK1 is a functionally versatile molecule that is able to contribute to the activity of several TNFR1 signaling complexes, some of which require its kinase activity and others that do not. In complex I, RIPK1 acts to recruit additional signaling components to the TNFR1 complex in a kinase-independent manner once modified by TRAF2-mediated lysine 63–linked polyubiquitylation. One of these components is NF-κB essential modulator (NEMO), a component of the IκB kinase (IKK) complex that stimulates the phosphorylation, ubiquitylation, and degradation of IκBα to reveal the transcriptional activity of NF-κB. It is important to note that under these conditions, cell death does not proceed; instead, NF-κB induces the transcription of genes that contribute to cellular survival, including those that encode cIAP1, cIAP2, FLIP, and others that participate in inflammatory responses.

The critical physiologic importance of this signaling complex is evidenced by the rescue of embryonic lethality in NF-κB–deficient mice by the co-deletion of TNFR1. However, the embryonic lethality induced by the deletion of NF-κB can be distinguished from that associated with TRAF2, cIAP1, and cIAP2 disruption, indicating that TNFR1-mediated survival may also proceed in an NF-κB–independent manner.

Under some conditions the TRADD-TRAF2-RIPK1 signaling complex is released from TNFR1, with the DD domain of TRADD, which is available after detachment from TNFR1, now recruiting FADD. This scenario is then compatible with the formation of one of two signaling complexes, termed complex IIa and IIb (Figure 28-2B). Recruitment of the FLIP long form ($FLIP_L$) to form heterodimers with caspase-8 prevents the assembly of catalytically active caspase-8 homodimers to inhibit apoptosis, but in a manner that retains the ability of caspase-8 to cleave and inactivate RIPK1 and RIPK3 (involved in necroptosis; described later). However, in the absence of $FLIP_L$, the catalytic activity of caspase-8 is unrestrained and therefore able to promote apoptosis. In contrast, inhibition of caspase-8, or its requisite adapter, FADD, promotes assembly of complex IIb, also termed the *necrosome*, by allowing the recruitment and stabilization of RIPK1 and RIPK3 to instead trigger necroptosis (Figure 28-2C). In this way, $FLIP_L$ provides a critical point at which TNFR1 signaling events are integrated to determine the mode of cell death that is engaged.

### Molecular Interaction with the Mitochondrial Pathway—Caspase-8/BID

For the most part, the apical signaling events of the intrinsic and extrinsic apoptotic pathways proceed independently of one another, converging only at the terminal executioner phase of caspase-3 activation. However, MOMP, although typically associated with the intrinsic death pathway, can also participate in death receptor–mediated apoptosis by virtue of caspase-8–mediated cleavage and activation of the BH3 protein, BID (Figure 28-1). The functional importance of this mitochondrial component of the death signaling pathway differs between cell types, leading to the classification of type I and type II cells—those that engage death receptor–mediated cell death without the involvement of MOMP and those in which apoptosis induced by death ligands requires mitochondria as evidenced by their susceptibility to BCL-2–mediated inhibition, respectively. XIAP appears to be the critical determinant of the relative involvement of BID-mediated MOMP in the extrinsic apoptosis pathway.[90a] XIAP binds to and blocks the proteolytic activities of caspase-9, -3, and -7 but not caspase-8—that is, unless displaced by SMAC and OMI, both of which are released from the mitochondria upon MOMP. The ability of MOMP to promote death receptor–mediated apoptosis can occur independently of APAF-1, indicating that the antagonism of the function of XIAP to permit caspase-8–mediated activation of the executioner caspases represents the major role for MOMP in death receptor–mediated apoptosis in type II cells.

## NONCANONICAL FORMS OF CASPASE-MEDIATED CELL DEATH

### Cell Death, Inflammasomes, and Caspase-1 Activation

In addition to apoptosis, additional types of cell death are also mediated by the activity of caspase proteases, including caspase-1–dependent pyroptosis, as previously introduced. Recruitment of inactive procaspase-1 to a multiprotein complex called the inflammasome forces a self-cleavage event to generate catalytically active caspase-1. The most well-characterized role of bioactive caspase-1 is the processing and activation of its substrates IL-1β[91] and IL-18.[92,93] Release of these cytokines, in addition to other proteins lacking a signal peptide, including IL-33,[94] pro-IL-1α, and fibroblast growth factor (FGF)-2, occurs via a poorly understood noncanonical secretory pathway that also requires caspase-1 activity.[95]

Assembly and activation of the inflammasome complex to initiate the production of the pro-inflammatory cytokines, IL-1B and IL-18, represents a critical component of the host innate immune system to protect against infection and sterile insults. The initiating event for inflammasome assembly is the detection of a "stressor" by one of several sensor molecules or nucleotide-binding domain, leucine-rich repeat–containing (NBD-LRR), or NLRs. Activators of NLRs, collectively termed DAMPs, can be of endogenous, exogenous, self, or foreign origin, although most are commonly associated with components of infectious agents or pathogen-associated molecular patterns (PAMPs).

NLRs are among the so-called pattern recognition receptors (PPRs) that encompass TLRs, C-type lectin receptors (CLRs), the absent in melanoma 2 (AIM2)-like receptor (ALR) families, and retinoic acid inducible gene I (RIG-I)-like receptors (RLRs). NLR members include NLRP1 (NOD-, LRR-, and pyrin-containing domain 1), NLRP3, -6, -7, and -12 (also named IPAF) and are characterized by three distinct domains. The N-terminal region that confers the functional classification of the NLR contains a pyrin,

**Figure 28-2** Multiple tumor necrosis factor (TNF)-TNF receptor 1 (TNFR1) complexes can be formed, each leading to a different biologic outcome. **A,** Complex I: Binding of TNF to its trimeric receptor TNFR1 triggers assembly of complex I that comprises TNFR-associated death domain (TRADD), receptor-interacting protein kinase 1 (RIPK1), and the E3 ubiquitinases, cellular inhibitor of apoptosis 1 (cIAP1), cIAP2, TNFR-associated factor 2 (TRAF2), and HOIL-1 of the linear ubiquitin chain assembly complex (LUBAC). cIAP1/2 mediates the K63-linked polyubiquitylation of RIPK1 on lysine 377 to promote RIPK1-dependent stabilization of complex I and recruitment of the (1) TAB-TAK complexes and (2) nuclear factor-κB (NF-κB) activation of the IκB kinase (IKK) complex. The E3 ligase activity of the LUBAC further contributes to RIPK1 ubiquitination, complex stability, and NF-κB activation. NF-κB–dependent transcription of cellular FLICE-like inhibitory protein long form ($cFLIP_L$) and cIAP1 and -2 contribute to cellular survival by the stabilization of complex I and inhibition of proapoptotic complex II assembly. **B,** Complex IIa: The formation of complex IIa is triggered by TNF-TNFR1 interaction and occurs in the cytosolic compartment under conditions in which complex I is destabilized. One way this can occur is via the activity of CYLD, a deubiquitylase that removes K63-linked polyubiquitin from RIPK1 to promote the destabilization of complex I and dissociation of RIPK1 to participate in alternative TNF-induced signaling complexes. Complex IIa assembly involves the indirect recruitment of Fas-associated protein with death domain (FADD) to TNFR1 via TRADD. This activity promotes the association of procaspase-8 monomers to form catalytically active caspase-8 dimers. Active caspase-8 can then cleave and activate the downstream executioner caspase-3 and -7 to mediate apoptotic cell death. $FLIP_L$ can also bind to FADD and/or procaspase-8. Under these conditions, caspase-8 in dimerization with $FLIP_L$ is catalytically active but not fully processed, displays altered substrate specificity, and cannot engage apoptosis. Complex IIb (ripoptosome): Under conditions in which cIAPs are reduced or inhibited, stable RIPK1-dependent complex I formation is less favored and an alternative complex IIb can assemble. This cytosolic complex is TRADD-independent and comprises RIPK1, FADD, and $FLIP_L$–caspase-8 heterodimers. Under these conditions the proapoptotic RIPK1 function is favored. $FLIP_L$ can also bind to FADD and acts as a competitive inhibitor of caspase-8-FADD association to prevent apoptosis. Changes in the levels of RIPK3, mixed lineage kinase domain-like (MLKL), and caspase-8 activation can alternatively lead to necroptosis. **C,** TNF-induced necroptosis: induction of necroptosis in response to TNF-TNFR1 ligation. Oligomerization of RIPK1 and RIPK3 induces the autophosphorylation of RIPK3 to recruit and phosphorylate MLKL in an RIPK3-dependent manner. How MLKL then induces rupture of the plasma membrane remains unclear, but suggested mechanisms include direct permeabilization by MLKL itself or MLKL-dependent recruitment of $Ca2^+$ and/or $K^+$ ion channels to effect changes in ion homeostasis, cellular swelling, and eventual rupture of the plasma membrane. NEMO, NF-κB essential modulator; SMAC, second mitochondrial-derived activator of caspase. *(From Weinlich R, Green DR: The two faces of receptor interacting protein kinase-1.* Mol Cell *56:469–480, 2014, and Pasparaki, M, Vandenabeele P: Necroptosis and its role in inflammation.* Nature *517:311–320, 2015.)*

CARD, or baculovirus inhibitory domain, the central domain, an NBD or NACHT domain (nucleotide-binding domain) that mediates deoxyribonucleotide triphosphate (dNTP) hydrolysis and multimerization, and the C-terminal LRR domain. It is the LRR domain, which is ascribed autoinhibitory function in several inflammasome complexes, that promotes structural stability and a variety of protein-protein interactions.

Despite significant advances in our understanding of inflammasome biology, several major questions remain unanswered. The precise manner by which inflammasome assembly is triggered after receptor activation remains somewhat of a mystery because no direct binding between the NLR and its cognate ligand has been identified. Furthermore, the precise circumstances governing the formation of one type of inflammasome in preference to another and their specific physiologic role(s) are also largely unclear. Regardless, it is clear that caspase-1 activities play a pivotal role in immune regulation. Later we discuss aspects of inflammasome biology in the context of caspase-1–mediated cell death and how their dysregulation may mediate the underlying pathophysiology of several autoinflammatory conditions.

The inflammasome, although structurally analogous to the caspase-8 activating DISC and the caspase-9 activating apoptosome in general terms, differs from these caspase-activation complexes in one significant way. The inflammasome complex can vary in its molecular composition by virtue of different adapter molecules that are themselves characterized by one of several different protein-binding domains (Figure 28-3). Despite the compositional variations of inflammasome complexes, their primary role is to induce caspase activity via direct or indirect interaction with the CARD domain of caspase-1. One of the most common adapter molecules required for inflammasome assembly is apoptotic speck-forming CARD (ASC), which mediates IL-1 and IL-18 processing via homomultimeric interactions between its CARD domain and that of caspase-1. ASC also contains a PYD, a DD that mediates interaction between the PYD domain of several members of the NLR family, including NLRP1, -3, -6, -7, and -12 and NLRC4, to promote inflammasome assembly. Activating ligands are derived from multiple sources and include endogenous ligands such as glucose and amyloid-β, environmental stressors including asbestos and ultraviolet irradiation, and those derived from infectious agents of bacterial, viral, fungal, and protozoan origin.

## Canonical NLRP3 Inflammasome

In most but not all cases,[96,97] assembly of an active NLRP3-containing inflammasome requires two independent signaling events. The first event primes the cells for inflammasome assembly and arises from NF-κB activation mediated by TLR or TNFR1 activation to induce NLRP3 expression.[98] The second event is mediated by activation of NLRP3 via one of several DAMPs or PAMPs. Whether NLRP3 is a receptor *per se* remains unclear, but inflammasome formation is induced in an NLRP3-dependent manner in response to multiple signaling molecules including asbestos,[99] amyloid-β,[100] uric acid,[101] muramyl-dipeptide,[102] and calcium pyrophosphate dihydrate (CPPD),[103] as well as bacterial RNAs[104] and viral components derived from multiple pathogens. In response to these triggers, NLRP3, via its PYD domain, associates with the PYD-containing adapter ASC. The CARD domain of ASC then interacts with that of caspase-1 to promote inflammasome formation and the processing of IL-1β/IL-18.

The promiscuous nature of NLRP3 activation is likely to represent a common activation mechanism rather than mul-

tiple factors directly interacting with NLRP3 to promote inflammasome assembly. However, despite this assertion, a unifying mechanism has yet to emerge, although many potential triggers have been proposed (Figure 28-2A). These potential triggers include several mitochondrially localized events such as reactive oxygen species (ROS) production,[105] oxidation of mitochondrial DNA,[106] translocation of cardiolipin,[107] and direct association between K63 ubiquitinated NLRP3[108] and mitochondrial anti-viral signaling (MAVS) proteins[109] or mitofusin 2.[110] Molecules shown to physically interact with NLRP3 to promote inflammasome assembly include double-stranded RNA-dependent protein kinase (PKR)[111] and guanylate binding protein (GBP).[112] Several additional regulatory factors include $K^+$ efflux,[113,114] $Ca^{2+}$ influx,[115,116] ATP-triggered puraminergic signaling events,[117] and interaction with chaperone proteins including HSP90 and SGT1 via the LRR domain of NLRP3 to maintain a stable but inactive complex.[118]

Recently, a completely independent signaling pathway has been implicated in the regulation of NLRP3-mediated

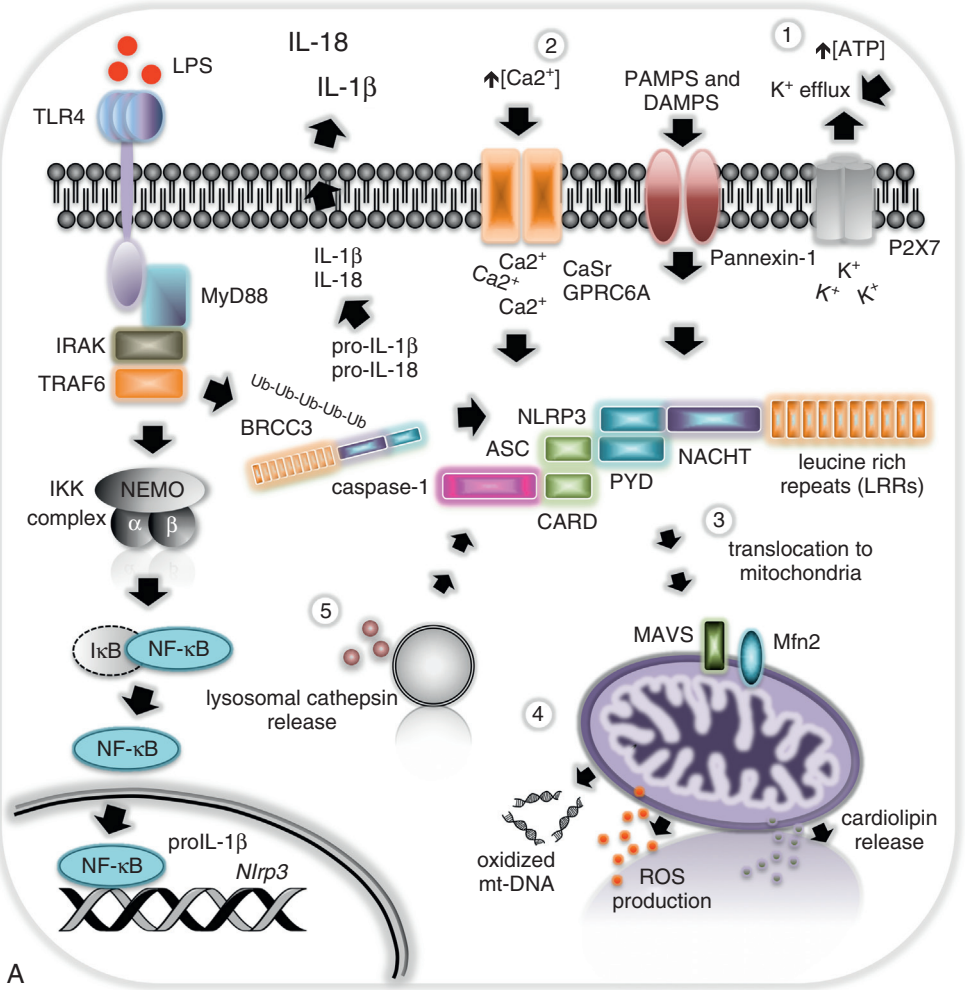

**Figure 28-3** The inflammasome is the activation platform for caspase-1 and is represented by different complexes according to the identity of the specific NLR and adapter proteins. **A,** NLRP3 (NALP3 canonical inflammasome). NLRP3 inflammasome assembly is induced by viral and bacterial pathogen-associated molecular patterns (PAMPs) and danger-associated molecular patterns (DAMPs) arising from environmental and self-derived origins. Examples include pore-forming toxins, amyloid aggregates, extra-cellular adenosine triphosphate (ATP), hyaluronan, monosodium urate (MSU) crystals, asbestos, silica, alum, and ultraviolet irradiation. NLRP3 inflammasome assembly is mediated by interaction between the PYD domains of NLRP3 and apoptotic speck-forming CARD (ASC) and a CARD-CARD interaction between ASC and caspase-1. This results in the activation of caspase-1, cleavage of pro-IL-1β and pro-IL-18, and their subsequent release as bioactive molecules. How NLRP3 is activated in response to all these different stimuli is unclear, although several mechanisms have been proposed: (1) elevation in extra-cellular ATP triggers $K^+$ efflux via the ATP-gated $K^+$ channel, P2X7, and assembly of pannexin-1 pores, through which PAMPs and DAMPs may enter the cytosol; (2) increased availability of $Ca^{2+}$ ions from endogenous stores and extra-cellular sources also activates NLRP3 inflammasome assembly, and several mechanisms have been proposed, including entry of extra-cellular calcium via the G-protein coupled calcium-sensing receptors (CaSRs); mitochondria may function as a source of several activating stimuli; (3) interaction of NLRP3 with mitochondrial anti-viral signaling (MAVS) proteins or mitofusin 2 (Mfn2) or (4) in response to the mitochondrial release of cardiolipin, reactive oxygen species (ROS), or oxidized DNA; and (5) lysosomal rupture and release of cathepsins. In addition to one or more of these activating stimuli, a nuclear factor-κB (NF-κB) priming signal, triggered via Toll-like receptors (TLRs) or tumor necrosis factor receptor 1 (TNFR1; lipopolysaccharide [LPS]-mediated TLR4 activation is shown) induces the transcription of NLRP3 and pro-IL-1β. Deubiquitination of NLRP3 via BRCC3 is also required to permit assembly of the NLRP3 inflammasome.

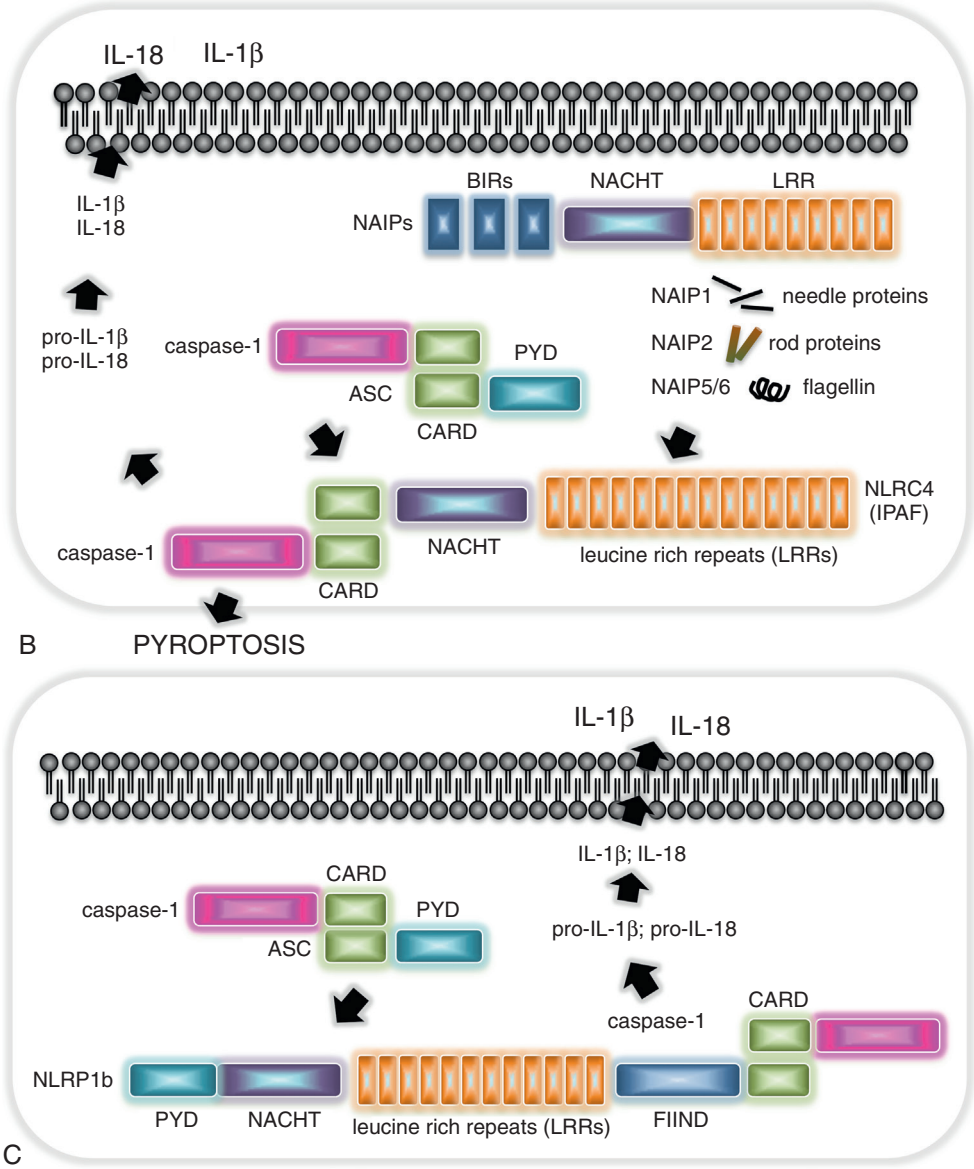

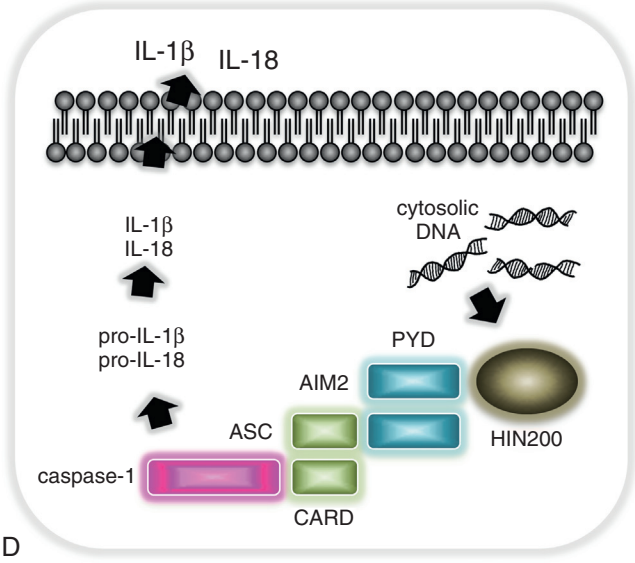

**Figure 28-3, cont'd** **B,** NLRC4 inflammasome. Flagellin and components of the type III and type IV bacterial secretion machinery trigger NLRC4 inflammasome assembly via the NACHT domain of the neuronal apoptosis inhibitory proteins (NAIPs). NAIP1 acts as the upstream sensor of needle proteins, those of NAIP2 sense rod proteins, and NAIP5/6 BIRS are triggered by flagellin. Interaction between the NIAPs and NLRC4 may then trigger oligomerization of NLRC4, and direct interaction between the caspase recruitment domains (CARDs) of NLRC4 and caspase-1 then complete assembly of the inflammasome and IL-1β/IL-18 secretion. Under some circumstances, ASC can also play a role. **C,** NLRP1b inflammasome. Activators include ATP, bacterial peptidoglycan dipeptide (MDP), and lethal toxin from *Bacillus anthracis*. Caspase-1 CARD can directly interact with NLRP1b CARD to form the inflammasome. ASC may stabilize this interaction and potentiate inflammasome activity. Cleavage of the FIIND domain of NLRP1b may be required for its activity.

inflammasome assembly that directly couples it to the regulation of cell death. The functional integration of recognized components of cell death signaling with inflammasome regulation was first uncovered by the demonstration that lipopolysaccharide (LPS; signal 1) in combination with a SMAC mimetic to promote the degradation of cIAP1 and -2 regulated IL-1β processing. Significantly, IL-1β maturation and secretion was mediated in both an NLRP3–ASC–caspase-1–dependent and caspase-8–dependent—caspase-1–independent manner.[119] RIPK3 and ROS generation was required under both conditions. Subsequently, both FADD[120] and caspase-8[120,121] have been shown to be essential for TLR-initiated NLRP3 inflammasome assembly. However, this may not be the case in all cell types.[122]

Multiple inherited and de novo mutations in the *NLRP3* gene have been identified, many clustered within the NBD domain, rendering a genetic predisposition to increased formation of the NACHT, LRR, and PYD domain-containing protein 3 (NALP3)-containing inflammasome. Increased IL-1β production contributes to the pathophysiology of a family of cryopryinopathies or cryopyrin-associated periodic

D

**Figure 28-3, cont'd** **D,** Absent in melanoma 2 (AIM2) inflammasome. Activators of the AIM2 inflammasome include DNA from intra-cellular bacteria and viruses, as well as self-derived double-stranded DNA. Cytosolic DNA binds to the HIN200 domain of AIM2 to trigger its interaction with ASC via their respective PYD domains. Caspase-1 is then recruited via its CARD domain to bind with the CARD domain of ASC. Activation of caspase-1 then processes pro-IL-1β and pro-IL-18 to generate the mature proteins. IKK, IκB kinase; IL, interleukin; IRAK, interleukin-1 receptor-associated kinase; LRR, leucine rich repeat; mt-DNA, mitochondrial DNA; NEMO, NF-κB essential modulator; TRAF, TNFR-associated factor. *(From Wen H, Miao EA, Ting JP: Mechanisms of NOD-like receptor-associated inflammasome activation.* Immunity *39:432–441, 2013, and Lamkanfi M, Dixit VM: Modulation of inflammasome pathways by bacterial and viral pathogens.* J Immunol *187:597–602, 2011.)*

fever syndromes (CAPS) including familiar cold-induced autoinflammatory syndrome (FCAS), Muckle–Wells syndrome (MWS), and neonatal onset multisystem inflammatory disorder or chronic infantile neurologic cutaneous and articular syndrome (NOMID/CINCA).[123] Genetic characterization of a contributory role for NLRP3 in CAPS was identified using murine knockin models harboring specific NLRP3 mutations associated with MWS and FCAS.[124] These NLRP3 mutations, when introduced into cells of the hematopoietic compartment, manifested in several clinical features of the human syndromes, including neutrophil infiltration into the skin, periodic bouts of fever, and elevated Th17-associated cytokines. These symptoms were largely alleviated by anti–IL-1 treatment, suggesting that the underlying pathophysiology can be attributed to increased IL-1β secretion as a consequence of the enhanced formation of NLRP3-containing inflammasomes.

Several other pathophysiologies associated with exuberant production of pro-inflammatory cytokines, including IL-1β, have also implicated NLRP3 function. NLRP3-dependent inflammasome formation can be triggered by the mislocalization of endogenous molecules, including those typically associated with gout, an inflammatory disease arising from deposition of monosodium urate (MSU) crystals in the joints, cholesterol deposits in atherosclerotic plaques, and insoluble aggregates of β-amyloid, a feature of Alzheimer's disease. Tissue damage arising from ischemic-reperfusion injury or that associated with excessive inflammation in the lung during pulmonary fibrosis or asthma is characterized by the release of multiple DAMPs, including extra-cellular ATP, uric acid, the purinergic receptor P2X7, and hyaluronan, a component of the extra-cellular matrix—all of which can directly induce the formation of an NLRP3-dependent inflammasome. Furthermore, lung inflammation arising from environmental factors such as asbestos and silica may well be attributable to the reported NLRP3-dependent production of IL-1β and IL-18 triggered by these agents. Although a direct role for NLRP3 in all of these aberrant inflammatory scenarios remains to be fully tested, a contributory role in the associated pathophysiologies seems likely.

The NLRP3-containing inflammasome is an essential component of the host immune response to numerous bacterial, fungal, and viral pathogens. Examples include *Staphylococcus aureus*, *Listeria monocytogenes*, *Escherichia coli*, *Klebsiella pneumonia*, *Shigella flexneri*, *Candida albicans*, and *Saccharomyces cerevisiae*.[125] Several of these organisms express pore-forming toxins that have been shown to induce membrane rupture and NLRP3-dependent inflammasome activation and/or pyroptosis. These include toxins A and B from *Clostridium difficile*,[126] pneumolysin from Streptococcus pneumonia,[127] nigericin from various strains of Streptomyces,[128] α-, β- and γ-hemolysins, the virulence factors from *S. aureus*,[129] and listeriolysin from *L. monocytogenes*.[130]

Host-mediated immunity against some DNA viruses including influenza,[131,132] herpes,[133,134] and sendai[135] may also involve activation of the NLRP3 inflammasome.[136] However, identification of AIM2 as the primary sensor of nucleic acids to trigger ASC-dependent inflammasome activation[137] may limit the general role of NLRP3 under some conditions. Nevertheless, clearly NLRP3 is a critical component of effective host defense against multiple bacterial pathogens and DAMPs of self-derived origin.

## NLRC4 (IPAF or CARD12 Inflammasome)

In contrast to the requisite ASC-dependent activation of caspase-1 in the NLRP3 inflammasome, NLRC4 itself contains a CARD domain that is capable of direct interaction with the CARD of caspase-1, leading to its processing and the cleavage and secretion of IL-1β and IL-18.[138,139] However, under certain conditions, NLRC4 and ASC may interact via their respective CARD domains in a manner that does not prevent the interaction of ASC with caspase-1. Such a scenario makes provision for an alternate biologic outcome based on ASC activity. For example, ASC-dependent inflammasome formation is required for IL-1β/IL-18 generation, whereas pyroptosis can proceed in its absence.[140]

Cytosolic assembly of the NLRC4 inflammasome is triggered by components of the type III or type IV secretion systems or by flagellate bacteria including *Shigella flexneri*, *Pseudomonas aeruginosa*, and *Salmonella typhimurium*. NLRC4 is a unique member of the NLR family in that the mechanism mediating its response to pathogens is known. Members of the NLR-apoptosis inhibitory protein (NAIP) family, 6 paralogs in mice, function as the upstream sensors to then directly engage NLRC4 inflammasome assembly and IL-1β maturation.[141] NAIP proteins are characterized by an N-terminal domain containing three BIR repeats, a

nucleotide-binding oligomerization domain (NOD) harboring multiple α-helices, and a C-terminal LRR. NAIP1[142,143] responds to the needle proteins and NAIP2 responds to the rod proteins[144-147] of the bacterial type III secretion system, whereas NAIP5 and -6 are sensors for bacterial flagellin.[147] Association of the NAIP with its respective ligand is mediated by the NBD and not the BIR domains as previously thought and triggers subsequent interaction with NLRC4 to promote inflammasome assembly.[148] The precise details of the NAIP-NLRC4 interaction remain unclear but may involve permissive phosphorylation by protein kinase C (PKC)-δ,[149] at least under some circumstances.[150]

Two independent NLRC4 gain-of-function point mutations were recently described, both of which rendered the NLRC4 inflammasome constitutively active and were associated with periodic bouts of fever.[151-153] Functional analyses revealed aberrant IL1-β/IL-18 production and an increased susceptibility to pyroptosis within macrophage populations isolated from patients.

## NLRP1b Inflammasome

NLRP1, the first NLR to be identified as an inflammasome mediator,[154] is encoded by a single gene in humans but by three orthologs in the mouse, denoted *Nlrp1a*, *Nlrp1b*, and *Nlrp1c*.[155] Unlike human NLRP, which contains a pyrin domain, the murine paralogs do not contain this domain and are composed of an NBD, an LRR region, a FIIND ("function to find" domain) and a C-terminal CARD. The *Nlrp1b* locus is most frequently associated with inflammasome formation and activation of caspase-1, although aspects of its regulation and function remain unclear. Muramyl dipeptide (MDP), a minimal bioactive peptidoglycan peptide common to both positive and negative bacteria, was initially identified as a ligand for NLRP1b-mediated inflammasome formation. However, whether NLRP1b-mediated inflammasome formation and caspase-1 processing requires pyrin domain–dependent association with ASC or instead occurs via a direct interaction between NLRP1 and caspase-1 via their respective CARD domains remains unclear.[156] Conflicting studies, using cells lacking NLRP1 expression, report that MDP-mediated caspase-1 processing was instead dependent upon NLRP3, either alone or in cooperation with NOD2.[157,158]

Lethal toxin (LT), the major virulence factor of *Bacillus anthracis*, is a potent ligand for NLRP1b-dependent inflammasome formation and triggers IL-1β and IL-18 processing and extensive pyroptosis of macrophages. LT promotes the cleavage of NLRPb1,[159,160] an event that is reportedly both necessary and sufficient[161] for inflammasome assembly. Although autoproteolysis of NLRP3 also correlates with susceptibility to LT-induced inflammasome assembly, it is insufficient for pro-IL-1β activation.[162-164] Additional parameters that contribute to the susceptibility of cells to LT, inflammasome formation, and pyroptosis include extra-cellular ATP release and reduced p38-mediated survival.[165]

The physiologic significance of NLRP1b inflammasome activity in response to LT is supported by the observed resistance to *B. anthracis* infection in mice expressing an LT-sensitive allele of NLRP1b.[166] However, other studies have noted that resistance to *B. anthracis* and IL-1β production does not necessarily correlate with NLRP1b activation,[155] suggesting the contribution of additional factors.

NLRP1a is also associated with inflammasome formation and the consequent secretion of IL-1β and IL-18 in an ASC-independent manner.[167] Regulation of NLRP1a activity is effected at multiple levels, including induction of its expression via NF-κB promoter elements, activation by post-translational autoprocessing. and inhibition via LRR-mediated association with the anti-apoptotic BCL-2 family members, BCL-2 and BCL-$X_L$. Interestingly, an activating mutation of NLRP1 and consequent predisposition to inflammasome formation, although associated with lethal systemic inflammation via IL-1β, also led to caspase-1 activity and extensive pyroptosis in the hematopoietic compartment independently of IL-1β. NLRP1a-mediated inflammasome formation and pyroptosis therefore may have additional roles independent of that in IL-1β–mediated inflammation.

## NLRP6 Inflammasome

NLRP6 is expressed predominantly in gut epithelial cells and can mediate ASC-dependent assembly of the inflammasome, caspase-1 processing, and enhanced secretion of IL-1β and IL-18. However, until recently, the physiologic significance of NALP6 remained elusive. Mice lacking NLRP6, ASC, or caspase-1 exhibited a marked exacerbation in colitis and an enhanced susceptibility to damage-associated gut tumorigenesis.[167a,167b,167c,167d] This outcome was attributed to the disruption of epithelial cell turnover and indicates that localized inflammation is critical for tissue repair. In contrast, the amelioration of colitis in mice lacking NLRP6 and IL-1β secretion aligns instead with the destructive consequences of the inflammatory response.[167e] One intriguing reconciliation of these opposing findings may lie in the observation that NLRP6, by promoting ASC-dependent inflammasome assembly and IL-18 secretion, regulates the gut flora to maintain integrity of the epithelial barrier and reduce the incidence of colitis.[167f] Therefore NLRP6 deficiency negatively regulates inflammasome assembly, promotes aberrant colonization of the gut by damage-inducing microbiota, and leads to a localized inflammatory response.

In contrast to what we believe to be the primary pro-inflammatory role of the other NLRs, NLRP6 instead negatively regulates inflammatory signaling to retard pathogen clearance. Accordingly, mice lacking *Nlrp6* are highly resistant to *L. monocytogenes*, *Salmonella typhimurium*, and *E. coli* that is attributed to NLRP6-mediated suppression of TLR-generated MAPK and NF-κB signaling events.[167g] Whether this finding is representative of a subclass of NLRs that function as critical immune suppressors remains to be determined. It does, however, provide tantalizing evidence of regulatory cross-talk between the NLRs and members of the TLR family.

## AIM2 (Pyrin) Inflammasome

AIM2, although not an NLR, is a pyrin-containing protein that is responsive to cytosolic DNA[168] of either pathogen or host origin and is able to mediate inflammasome formation.[169,170] AIM2, via its HIN-200 domain,[171] directly

associates with its trigger, DNA, to recruit the adapter ASC in a PYD-dependent manner to promote caspase-1 activation.[172,173]

AIM2, by regulating the levels of IL-1β and IL-18, plays a critical role in antipathogen immunity to several cytosol-replicating bacteria such as *Francisella tularenis*[137,174,175] and *L. monocytogenes* and the DNA viruses, vaccinia and cytomegalovirus.[137] The mechanism(s) via which AIM2 can sense cytosolic DNA has/have yet to be fully elucidated, although type I IFN signaling events can contribute to the response to bacterial DNA, although not to that of viral origin.[175,176] AIM2 inflammasome assembly is subject to negative regulation by factors of both host and pathogen origin, including the PYRIN domain-only proteins (POPs)[177] and HIN-200–containing proteins,[178] both of which compete with ASC for binding to AIM2.

The ability of AIM2 to recognize and respond to cytosolic DNA of host origin is thought to mediate the pathophysiology of self-driven inflammatory responses, including systemic lupus erythematosis[179] and psoriasis.[180] Several studies have also linked susceptibility to certain tumor types and AIM2-dependent inflammasome formation,[181,182] although a direct causative role has yet to be shown.

### Noncanonical Inflammasome

NLRP3, in addition to its critical role in canonical inflammasome assembly to activate caspase-1 (previously described), also participates in caspase-11–dependent noncanonical inflammasome formation.[183] The family of inflammatory caspases, in addition to caspase-1, includes murine caspase-11 and human caspase-4, -5, and -12. Caspase-11 can induce IL-1β–dependent pyroptosis in a caspase-1–dependent manner.[183a] Several pathogenic bacteria, including *E. coli*, *Vibrio cholera*, *S. typhimurium*, and *Legionella pneumophila* induce the activation of procaspase-11 via assembly of a noncanonical NLRP3 inflammasome. Constitutively low expression of caspase-11 is induced by several pro-inflammatory stimuli, including TLR4–TIR-domain–containing adapter-inducing IFN-β (TRIF) activation via LPS, IFNs, IFN-γ, and IFN-β that is at least partially dependent on NF-κB and signal transducer and activator of transcription (STAT) signaling. Lipid A, a core structural moiety of LPS, was identified as the requisite trigger for caspase-4, -5, and -11 activation and pyroptosis after challenge with Gram-negative bacteria. Recent observations demonstrate that the activation of these caspases may occur by a direct interaction between LPS and the CARD of the caspase itself.[183b] The initiation of a process by the very same molecule responsible for its execution introduces an unexpected twist in our understanding of caspase biology and to the fundamental regulation of innate immunity. Whether this observation is just the first to define caspases as a novel class of receptors for pathogen-derived PAMPs, as well as an additional pathway by which caspases can be activated, remains to be seen.

However, not all IL-1β production is mediated by activation of the cytosolic NLRs. In a recent study, caspase-8, in a complex with mucosa-associated lymphoid tissue (MALT)-1 and ASC, mediated the processing of IL-1β in a SYK-dependent manner via extra-cellular dectin-1 in response to fungi and mycobacteria.[184] It remains to be determined if this noncanonical caspase-8 inflammasome can be engaged in response to other extra-cellular pathogens in a dectin-1–dependent or dectin-1–independent manner or, indeed, if the activity of other apical caspases can be similarly co-opted for host immune defense.

## NONAPOPTOTIC CELL DEATH SIGNALING PATHWAYS

### Necrosis and Secondary Necrosis

As we discussed briefly in the introduction, necrosis is typically characterized by cellular swelling, rupture of the plasma membrane, and the consequent spilling of the intra-cellular contents into the surrounding milieu. Necrosis can be induced directly by multiple different stimuli, including ATP depletion, nutrient withdrawal, and excessive levels of ROS. However, necrosis can also occur as a consequence of apoptosis and is hence termed *secondary necrosis*. This type of necrotic cell death is most commonly observed in vitro, as most often, cells dying by apoptosis in vivo are rapidly removed by the activities of professional phagocytes. However, disruption of the normal function of these "garbage collectors" can instead lead to secondary necrosis. Cells undergoing secondary necrosis are characterized by chromatin condensation, a feature typically associated with apoptosis, and plasma membrane permeabilization, one of the hallmarks of necrosis. Several other forms of necrosis can proceed entirely independently of apoptosis and can be identified by several distinctive characteristics that can reveal the pathway by which the cell died.

### Necrosis and the Mitochondrial Permeability Transition

In some forms of caspase-independent cell death, including necrotic death as a result of ischemia/reperfusion injury, MOMP may occur as a result of activation of the permeability transition pore (PTP), a channel in the inner mitochondrial membrane that is susceptible to regulation by a number of stimuli, including high concentrations of calcium ions, ROS, and fluctuations in cellular pH, as well as in response to certain drugs.

The precise identity and, for that matter, the role of the PTP in cell death remains somewhat controversial. What appears to happen is that once it is open, the PTP induces a rapid loss in the permeability of the inner mitochondrial membrane and consequent dissipation of the transmembrane potential, or mitochondrial permeability transition (MPT). This process in turn triggers the influx of solutes and then water into the mitochondrial matrix, causing swelling and, ultimately, rupture of the outer mitochondrial membrane. Importantly, although this phenomenon results in the spilling of mitochondrial components into the cytosol, no strong evidence exists to indicate that it activates apoptotic signaling, as would be the case if MOMP were mediated in a BAX/BAK-dependent manner.

The PTP has been proposed to be composed of several components, including the F0F1 adenosine triphosphatase (ATPase) in the inner mitochondrial membrane. Other components may include an adenosine nucleotide transporter (ANT) that mediates the transfer of adenosine

diphosphate (ADP) and ATP across the inner mitochondrial membrane, and the outer mitochondrial membrane voltage-dependent anion channel (VDAC). However, the deletion of ANT or VDAC components fails to have an impact on PTP activity. In contrast, mitochondria lacking cyclophilin D, a matrix peptidylprolyl isomerase, display an abrogated MPT response to calcium. However, this defect does not extend to aberrant apoptosis or developmental abnormalities.

## Poly-ADP-Ribose Polymerase and Necrosis (Parthanatos)

The generation of ATP to provide the necessary energy to sustain normal cellular function is mediated by the collective activities of glycolysis, the Krebs cycle, and oxidative phosphorylation. Disruption of these pathways or an enhanced demand for intra-cellular energy consumption can lead to bioenergetic failure and the consequent engagement of necrosis. PARP is an essential enzyme for DNA repair, an energy-costly process that utilizes large amounts of nicotinamide adenine dinucleotide ($NAD^+$), thereby limiting mitochondrial ATP generation. As a consequence, cellular damage that demands excessive PARP-dependent DNA repair can disrupt oxidative phosphorylation, leading to necrotic cell death, also known as parthanatos (*thanatos*—personification of death).

Of course, nothing in biology is that simple. PARP can also regulate the sensitivity of cells to DNA damage–induced apoptosis via its direct interaction with p53. Under these circumstances, PARP-dependent ribosylation of p53 negatively regulates the function of p53 to direct DNA repair and inhibit p53-dependent apoptotic cell death. However, under conditions of irreparable DNA damage, the interaction between p53 and PARP may actually promote apoptosis. In a reciprocal manner, p53 function can positively regulate PARP activity to facilitate necrosis in response to DNA damage imposed by excessive production of ROS. Consistent with this, the resistance of $p53^{-/-}$ murine embryonic fibroblasts (MEFs) to $H_2O_2$-induced DNA damage correlates with DNA repair and the recovery of intra-cellular $NAD^+$ levels. Furthermore, loss of p53 activity, or disruption of the downstream mediators of p53-mediated apoptosis, BAK and BAX, correlate with a reduction in PARP activity. Therefore, the functional reciprocity between PARP and p53 regulates the cellular response to DNA damage to determine if DNA repair is compatible with survival or if cell death ensues. Furthermore, the type of death that is engaged—p53-dependent apoptosis or PARP-dependent necrosis—is directed by the complex interaction between these two proteins.

## Excitotoxicity and Necrosis

Excitotoxic death or excitotoxicity-induced necrosis is specific to neuronal cells and is induced by excessive levels of the primary excitatory neurotransmitter, glutamate or glutamate mimics, such as N-methyl-D-aspartate (NMDA) and kainic acid. The activity of glutamate is mediated by calcium-permeable ionotropic receptors that include the NMDA and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors (NMDAR and AMPAR). Glutamate triggers $Ca^{2+}$ influx that, under normal physiologic conditions, is buffered by a variety of sequestration and extrusion pathways to maintain normal $Ca^{2+}$ homeostasis. Mechanisms include sodium-calcium exchanger (NCX), which, after glutamate stimulation, extrudes calcium to help restore normal calcium levels, as well as mitochondria that both facilitate ATP-dependent calcium extrusion and act as a calcium sink to help reduce intracellular calcium levels.

Although glutamate is essential for a number of functions in neural tissues, the accumulation of excessive glutamate induces a massive influx of calcium that can trigger neuronal cell death or excitotoxicity. Glutamate also induces several morphologic changes, including neuronal swelling, a feature typically associated with necrosis. However, inhibition of neuronal swelling by the removal of extra-cellular $Na^+$ does not suppress glutamate-induced $Ca^{2+}$-dependent excitotoxic death, suggesting that this event is independent and not causative. Glutamate receptors consist of several subtypes, of which NMDAR is the most calcium permeable and most often associated with excitotoxic neuronal death. However, NMDAR activation is not always cytotoxic and under some conditions is reported to promote neuronal survival. This outcome may be attributable to the suggestion that only extrasynaptic NMDARs, activated by excessive levels of glutamate that spill beyond the synaptic space, are associated with the $Ca^{2+}$ signaling that triggers excitotoxicity.

Although $Ca^{2+}$ clearly plays a critical role in glutamate-mediated neurotoxicity, the precise molecular pathways that mediate this type of death remain to be fully delineated. Nicotinamide adenine dinucleotide phosphate (NADPH) oxidase is a membrane-bound enzyme that catalyzes the transfer of one electron from NADH or NADPH to oxygen to generate superoxide, a species of ROS. Unlike the analogous mitochondrial NADPH oxidase reaction that functions as part of the electron transport chain to generate energy, the production of superoxide by the nonmitochondrial form of NADPH instead generates protons. To prevent their accumulation, protons are pumped from the cell, but in so doing, a high transmembrane potential is generated. It is this large charge difference across the plasma membrane that is detected as an excitotoxic signal in glutamate-exposed neurons. The generation of superoxide by NADPH oxidase triggers PARP activation that, in turn, depletes intra-cellular ATP and induces necrotic cell death (discussed previously). Loss or attenuated production of ATP also limits the energy required for maintaining essential electrochemical gradients, including those that support the function of glutamate transporters. This limitation not only prevents extra-cellular glutamate uptake but also promotes the reversal of transporter function, further increasing the concentration of extra-cellular glutamate and exacerbating excitotoxic death.

Uptake of calcium by mitochondria during excitotoxic glutamate signaling can also trigger the generation of ROS, causing opening of the PTP, mitochondrial depolarization, $Ca^{2+}$ efflux, and neuronal cell death. $Ca^{2+}$ is required for the activation of calpain proteases, which are able to cleave and inactivate various target proteins. Calpain substrates suggested to contribute to glutamate-induced neuronal cell death include the NCX (previously described), p35, a regulator of CDK5, and the NMDAR.

Because NMDAR permeability is specifically associated with the $Ca^{2+}$ fluxes, promoting excitotoxic neuronal death, it is proposed that a close functional and/or physical association likely exists with death-signaling proteins. Consistent with this proposal, the cytoplasmic tail of the NMDAR can directly bind to death-associated protein kinase 1 (DAPK1), CDK5, or phosphatase and tensin homolog (PTEN) to regulate neuronal sensitivity to glutamate signaling. In addition, PSD95, a membrane-associated guanylate kinase, associates with both NMDAR and neuronal nitric oxide synthase (nNOS) to mediate glutamate-induced $Ca^{2+}$-dependent generation of NO. Peroxynitrite ($ONOO^-$), arising from a reaction between the free radical form of (NO*) and the superoxide anion, $NO^-$, is highly toxic, inducing damage to an array of biomolecules, including lipids and DNA. Significantly, ONOO-mediated DNA damage can engage PARP activity to promote neuronal necrosis, as previously discussed.

Excess levels of extra-cellular glutamate can arise from the disruption of its uptake, breakdown, and/or release. The aberrant accumulation of glutamate and resulting excitotoxic neuronal cell death is implicated in the cause of several pathologic conditions, including cerebral ischemia or stroke that is characterized by irreparable glutamine-dependent neuronal damage. Under these conditions, the release of glutamate from damaged neurons can stimulate additional glutamate release and accumulation, a scenario further exacerbated by additional factors associated with ischemic injury such as reduced availability of oxygen and glucose. The glucose dependence of glutamine breakdown can also manifest in hypoglycemia-associated neuronal cell death in persons with diabetes. Glutamine-induced cytotoxicity has also been implicated in several neurodegenerative diseases, including multiple sclerosis, Huntington's disease, Parkinson's disease, and amyotrophic lateral sclerosis (ALS).

## Ferroptosis

Ferroptosis or iron-dependent cell death is a relatively recently described type of nonapoptotic cell death that remains to be fully characterized.[185] Nonetheless, several characteristics of this type of cell death have been described, together with its clinical potential for the treatment of multiple types of disease, particularly those associated with aberrant iron accumulation.[186,187] Iron and iron derivatives are essential for the regulation of a number of ROS-producing enzymes, including lipoxygenases, subunits of the mitochondrial respiratory chain, NADPH, and the antioxidant, catalase. The identification and characterization of ferroptosis as a unique form of necrotic cell death arose from the identification of erastin, a small molecule specifically toxic to oncogenic RAS transformants, and hence termed *RAS-selective lethal* (RSL). Specific features of RSL-induced death include the accumulation of ROS independently of mitochondrial function and chelation of iron.[186,188] Ferrostatin-1, an inhibitor of ferroptosis, can also block glutamate-induced cell death in neurons (previously discussed), suggesting a similar underlying mechanism.[185,187]

Further characterization of ferroptosis has revealed that it is specific for iron and not other metals and can be distinguished from other forms of death, both apoptotic and necrotic, via morphologic and metabolic criteria. Cells undergoing ferroptosis are characterized by mitochondria that are smaller in size but with an increase in the density of their membranes. However, contrary to other forms of necrotic cell death, ferroptosis cannot be attributed to a drastic reduction in ATP levels and bioenergetic failure. The identification of several genes required for ferroptosis, including citrate synthase and an acyl Co-A synthase family member (ACSF2), both of which are involved in mitochondrial fatty acid metabolism, suggests that lipid synthesis could represent one pathway through which ferroptosis may be regulated. Further characterization indicates that ferroptosis is induced by iron-dependent production of lipid-derived ROS via the activities of several enzymes, including members of the NADPH oxidase family.

Additional scenarios in which aberrant regulation of iron levels are associated with cell death include hereditary hemochromatosis (HHC), a spectrum of diseases characterized by excess iron accumulation and diseases that include liver cirrhosis and heart failure. One suggested mechanistic link between excess iron and the associated tissue damage observed in HHC include iron-dependent ROS production and mitochondrial dysfunction, which both are features aligning with the characteristics of ferroptosis. Intriguingly, several neurodegenerative conditions, including Parkinson's disease, can be alleviated by the blocking of iron uptake, which also is suggestive of a causative role for ferroptosis.

## Programmed Necrosis or Necroptosis

Until relatively recently, our understanding of necrosis was somewhat limited, fueled largely by the presumed absence of any underlying molecular mechanism. However, the identification of regulated or programmed necrosis (necroptosis) has invigorated research efforts into determining the molecular basis for this type of death, how it contributes to host biology, and whether its regulatory pathways may be exploited for clinical benefit.[2,189]

Although several stimuli can induce programmed necrosis, TNF and activation of its death receptor, TNFR1, has provided most insight into the molecular basis of this type of necrotic cell death. As we have already discussed, TNFR1 signaling is complex, with TNFR1-induced NF-κB activation promoting cellular survival and death receptor–induced caspase-8 activation critical for the induction of apoptosis. However, long before we had defined its molecular basis or had a cool name for it, an alternative form of death receptor–induced death was also described that proceeded independently of caspase activation and required RIPK1 activity.[190-192] Recent genetic studies have characterized this form of TNF-induced caspase-independent cell death as necroptosis and defined key components of death receptor signaling, including caspase-8, FLIP, and FADD, as essential regulators.

## Were We Missing Something?

The tantalizing suggestion of an unidentified death pathway involving caspase-8, FADD, and FLIP arose from apparent contradictory findings that were not easily reconciled with their known role in apoptosis. These findings included the

unexpected embryonic lethality associated with the deletion of caspase-8 or FADD, two proteins that prior to these studies were exclusively associated with promoting apoptotic cell death and therefore were predicted to phenocopy the cellular accumulation observed in embryos lacking *Apaf-1* or *Caspase-9*.[193-195] These findings were reconciled by the genetic rescue of the early lethality of caspase-8 or FADD deficiencies by the co-deletion of either of two related kinases, RIPK1 and -3.[196-198] Programmed necrosis, or necroptosis, is therefore a death pathway that is mediated by RIPK1 and -3 but only in the absence of caspase-8 activity.

The overlapping requirement for several of the signaling components required for both TNF-induced apoptosis and TNF-induced necroptosis begs the question as to how the activity of caspase-8 is regulated under physiologic conditions to engage cell death via apoptosis or necroptosis, and even, under some circumstances, to sustain cellular survival. Presumably multiple checkpoints determine not only the makeup of the TNFR1 signaling complex but also the activity of these components to ensure an appropriate biologic response.

## Molecular Regulation of Programmed Necrosis

The realization that RIPK3 was required for TNF-induced RIPK1-dependent necrosis provided a critical piece of a mechanistic puzzle[199-201] that was completed by the subsequent identification of MLKL as the target of RIPK3 and terminal effector of necroptosis.[202,203] Interaction between catalytically active RIPK1 and RIPK3 is mediated by their respective receptor interacting protein (RIP) homotypic interaction motifs (RHIMs).[199,200,204] Neither the homodimerization of the N termini of RIPK1 lacking a RHIM domain (RIPK1$^{\Delta RHIM}$) nor heterodimerization of RIPK1$^{\Delta RHIM}$ and RIPK3$^{\Delta RHIM}$ is able to trigger necroptosis. However, enforced dimerization of either the N termini of RIPK1 or RIPK1$^{\Delta RHIM}$ and RIPK3 are both able to do so, as are homo-oligomers, but not dimers of the C termini of RIPK3$^{\Delta RHIM}$, as well as dimers of the N termini of RIPK3$^{\Delta RHIM}$.[205]

RHIM-dependent interaction between RIPK1 and RIPK3 kinases triggers the feed-forward self-propagation of large hetero-oligomeric RIPK complexes that are essential for both kinase activity and execution of necroptosis.[199,200,204] Characterization of these high-order RIPK1 and -3 oligomers revealed strikingly similar characteristics to amyloid aggregates and an underlying mechanism by which kinase activation and necrosome assembly mutually reinforce each other.[206] Amyloid-like structures can be toxic in and of themselves. However, acquisition of kinase activity as a consequence of RIPK1 and -3 complex assembly is more compatible with the requirement for specific RIPK substrates to mediate necroptosis, rather than the complexes themselves causing toxicity. Recently identified is the RIPK-dependent phosphorylation of the pseudokinase, MLKL, to induce its activation, oligomerization, and translocation to the plasma membrane.[202,203,207] The swelling and loss of membrane permeability in cells dying by necroptosis is attributed to the ability of MLKL to disrupt ion homeostasis. Whether this disruption occurs by the direct binding of MLKL to phospholipid components of the plasma membrane or by its association with $Ca^{2+}$ or sodium channels remains to be determined.[208-211]

## RIPK1—Apoptosis, Necroptosis, or Survival—Take Your Pick

Although the activity of RIPK1 is critical for TNFR1-mediated activation of RIPK3 and execution of necroptosis, it is now apparent that its ability to regulate cell death mechanisms also encompasses roles in TNF-induced apoptosis under certain conditions, as well as suppressing the aberrant inflammation associated with RIPK3 and caspase-8 activities. RIPK1 therefore clearly represents a critical signaling nexus within several pathways, including those induced by TNF, TLRs, DNA sensing pathways, and IFNs. The diverse consequences of its regulatory activities are evidenced by its impact on multiple downstream signaling pathways and their biologic consequences.[212]

Insight into the mechanisms by which RIPK1 activity can differentially regulate multiple signaling pathways are beginning to emerge. Deletion of RIPK1 is associated with perinatal lethality characterized by multiorgan inflammation and widespread cell death.[213] However, mice harboring one of several homozygous point mutations that eliminate RIPK1 kinase activity are viable.[214-216] Recent genetic studies have begun to elucidate not only the molecular basis for the postnatal lethality associated with RIPK1 deletion but also the identity of signaling pathways regulated by RIPK1 and the mechanisms mediating its effects. Although the individual deletion of FADD, RIPK3, or caspase-8 all fail to affect the lethal phenotype observed in *RIPK1*$^{-/-}$ mice, the ablation of both RIPK3 and caspase-8 or RIPK3 and FADD in the context of *RIPK1*$^{-/-}$ completely rescues postnatal lethality.[217-219] Development also proceeds normally in mice lacking both RIPK1 and RIPK3 and the requisite adapter molecule for caspase-8 activation, FADD.[217] The unambiguous conclusion from these studies is that RIPK1 is an inhibitor of two independent pathways associated with embryonic lethality—one that is mediated by FADD/caspase-8 and the other, a lethal RIPK3-mediated pathway. This conclusion is consistent with roles for RIPK1 in the inhibition of both apoptosis and necroptosis. However, have we not just discussed the requirement for RIPK1 in *promoting* cell death? In fact, this assertion also is supported by unambiguous genetic data—specifically, that the embryonic lethality associated with ablation of caspase-8 or FADD is completely rescued by the co-deletion of RIPK3 or RIPK1.[197,198] The simple conclusion, then, is that RIPK1 must drive or mediate the lethal signal resulting from the ablation of caspase-8 or FADD. Must we therefore reach the "not so simple" conclusion, then, that RIPK1 can both promote and inhibit cell death? As we will now discuss, that is indeed the case.

Homodimerization and activation of caspase-8 can be triggered by the ligation of TNFR1 via the adapter proteins TRADD and FADD to promote apoptosis.[194,220,221] NF-κB, which is also activated by TNFR1 ligation, can inhibit caspase-8–dependent cell death by inducing transcription of FLIP, a catalytically inactive form of caspase-8. FLIP, by forming heterodimers with caspase-8, prevents the homodimerization of caspase-8 to inhibit apoptosis. RIP1K, by acting as a scaffold protein within this signaling complex,

may provide a critical activation signal for NF-κB[222] or facilitate amplification of NF-κB–mediated transcription.[223-225] Either way, RIPK1 activity can contribute to cellular survival under conditions of TNFR1 ligation. MEFs deficient for RIPK1, but not those expressing a kinase-dead version of RIPK1, are more sensitive to TNF-induced apoptosis.[223] Furthermore, intestine-specific ablation of RIP1K in adult mice is associated with a postnatal lethality, characterized by extensive apoptosis of the gut epithelium and generalized inflammation. This RIPK1 null phenotype can be rescued by the tissue specific co-deletion of caspase-8 or FADD but not by the introduction of catalytically inactive RIPK1.[226,227] The observed accumulation of cIAP1 and TRAF2 in tissues lacking RIPK1 is consistent with a model in which the alleviation of cIAP1/TRAF2–mediated stabilization of NF-κB–inducing kinase (NIK) leads to increased NF-κB activity that in turn promotes TNF transcription to induce apoptosis. This model is supported by the rescue, albeit partial, of the excessive apoptosis associated with gut-specific ablation of RIPK1, as well as *Ripk1*$^{-/-}$/*Ripk3*$^{-/-}$-induced lethality, by the co-deletion of TNFR1.

RIPK1 can also mediate FADD-dependent caspase-8 activation to promote apoptosis in response to several stimuli, including depletion of cIAPs, TNF, and TLR activation.[228-230] Homotypic interaction between the DDs of FADD and RIPK1 to recruit and activate procaspase-8 constitutes the so-called "ripoptosome." TLR-induced ripoptosome formation is mediated by interaction of the respective RHIM domains of TRIF and RIPK1.[231-233] This prodeath role of RIPK1 is substantiated by several genetic studies in which the absence of RIPK1 (or caspase-8) can rescue the embryonic lethality associated with catalytically inactive RIPK3$^{D161N}$.[215] In a similar manner, ablation of MLKL, which is the target of RIPK3 and is required for necroptosis, instead can promote apoptosis via an RIPK3/RIPK1/caspase-8–dependent pathway.[234]

The death-inducing role of RIPK1 is also evident in RIPK3/MLKL–dependent necroptosis, but only under circumstances in which caspase-8 activity is disrupted. RHIM-mediated interaction between the RIPK1 and RIPK3 is essential for RIP3K activity and the induction of necroptosis by ligation of TNFR1. For this, RIP1K absolutely requires its kinase activity, although the precise reason remains unclear, because RIPK1-mediated phosphorylation of itself, but not RIPK3, can be detected. Potentially, therefore, autophosphorylation and a consequent conformational change of RIPK1 may mediate its interaction with RIPK3, or alternatively, additional RIPK1 substrates that participate in the activation of RIPK3 to promote necroptosis remain to be identified.

## RIPK1-Independent Necroptosis

Whereas the ubiquitous activity of RIPK1 can be utilized for cellular survival, apoptosis, or programmed necrosis, RIPK3/MLKL–dependent necroptosis can also proceed in the absence of RIPK1[235] (Figure 28-4A). TRIF, the signaling adapter associated with activation of TLR3 or -4, can directly bind and activate RIPK3 to promote necroptosis in the absence of RIPK1.[236] TRIF-independent TLR signaling can also induce necroptosis by autocrine or paracrine-mediated TNF activities.[237] The DNA sensor, DNA-dependent activator of IFN-regulatory factors (DAI), is activated by viral infection and contains an RHIM domain that can also directly engage RIPK3 function to promote necroptosis in the absence of RIPK1.[238-240] Type I (α/β) and II (γ) IFNs can also engage necroptosis under conditions in which either caspase-8 or FADD are inactivated. Although IFN-induced necroptosis is mediated via a RIPK1-RIPK3 complex, the kinase activity of RIPK1 is not required. Instead, the RNA-responsive kinase (PKR) interacts with RIPK1 to induce the formation of RIPK1-RIPK3 heterodimers and necroptosis.[235,241] If RIPK1 is present under any of these circumstances, necroptosis can only proceed if the proapoptotic FADD–caspase-8–FLIP axis is disrupted.

These observations are consistent with RIPK1-dependent inhibition of RIPK3/MLKL–mediated necroptosis. RIPK1 can suppress RIPK3-mediated necroptosis via two known pathways. The first requires its association with FADD to assemble the FADD–caspase-8–FLIP complex to facilitate the formation of FLIP–caspase-8 heterodimers (Figure 28-4B). These heterodimers, although unable to cleave and activate caspase-8 to promote apoptosis,[242-244] are sufficiently active to cleave components of the necrosome and its regulators,[198,245] including both RIPK1 and RIPK3, and suppress MLKL-mediated necroptosis.[246-248] In an alternative scenario, necroptosis initiated by caspase inhibition and TLR ligation or IFN treatment is inhibited by the disruption of RIPK1 activity with the RIPK1 inhibitor necrostatin (Figure 28-4C).[236,237,249] Furthermore, a catalytically inactive RIPK1 mutant, or RIPK1 bound to necrostatin, can still associate with RIPK3 when triggered by TLR signaling and caspase inhibition, but it does so in a manner that precludes interaction between RIPK3 and MLKL.[217]

## Pro-inflammatory Effects of Programmed Necrosis

Insight into the molecular mechanisms of programmed necrosis, although informative, is fueling the need for constant reevaluation of the critical factors required for programmed necrosis. As yet, a complete understanding of the role of programmed necrosis in regulating immune function remains to be delineated. However, with the validation of shared signaling components in necroptosis and pro-inflammatory pathways, it seems reasonable to speculate that we are only at the very beginning of appreciating the ramification of programmed necrosis in the context of immune regulation and how disruption of these pathways may underlie the etiology of numerous pathophysiologies.

Murine models in which the expression and/or function of RIPK3 or MLKL are disrupted have provided at least some insight into the in vivo role of necroptosis in inflammation. Deletion of RIPK3 prevents the spontaneous inflammation associated with tissue-specific deletion of FADD in the intestinal epithelial compartment[250] and skin keratinocytes,[251] consistent with a pro-inflammatory role of necroptosis. Similarly, the inflammatory consequences of tissue-specific deletion of caspase-8 in either the gut or the skin are abrogated by the co-deletion of RIPK3.[252] Deletion of RIPK3 or MLKL also ameliorated necroptosis of keratinocytes and immune infiltration into skin deficient for epidermal RIPK1.[226] Necrostatin has also been a useful tool with which to interrogate the significance or necroptotic

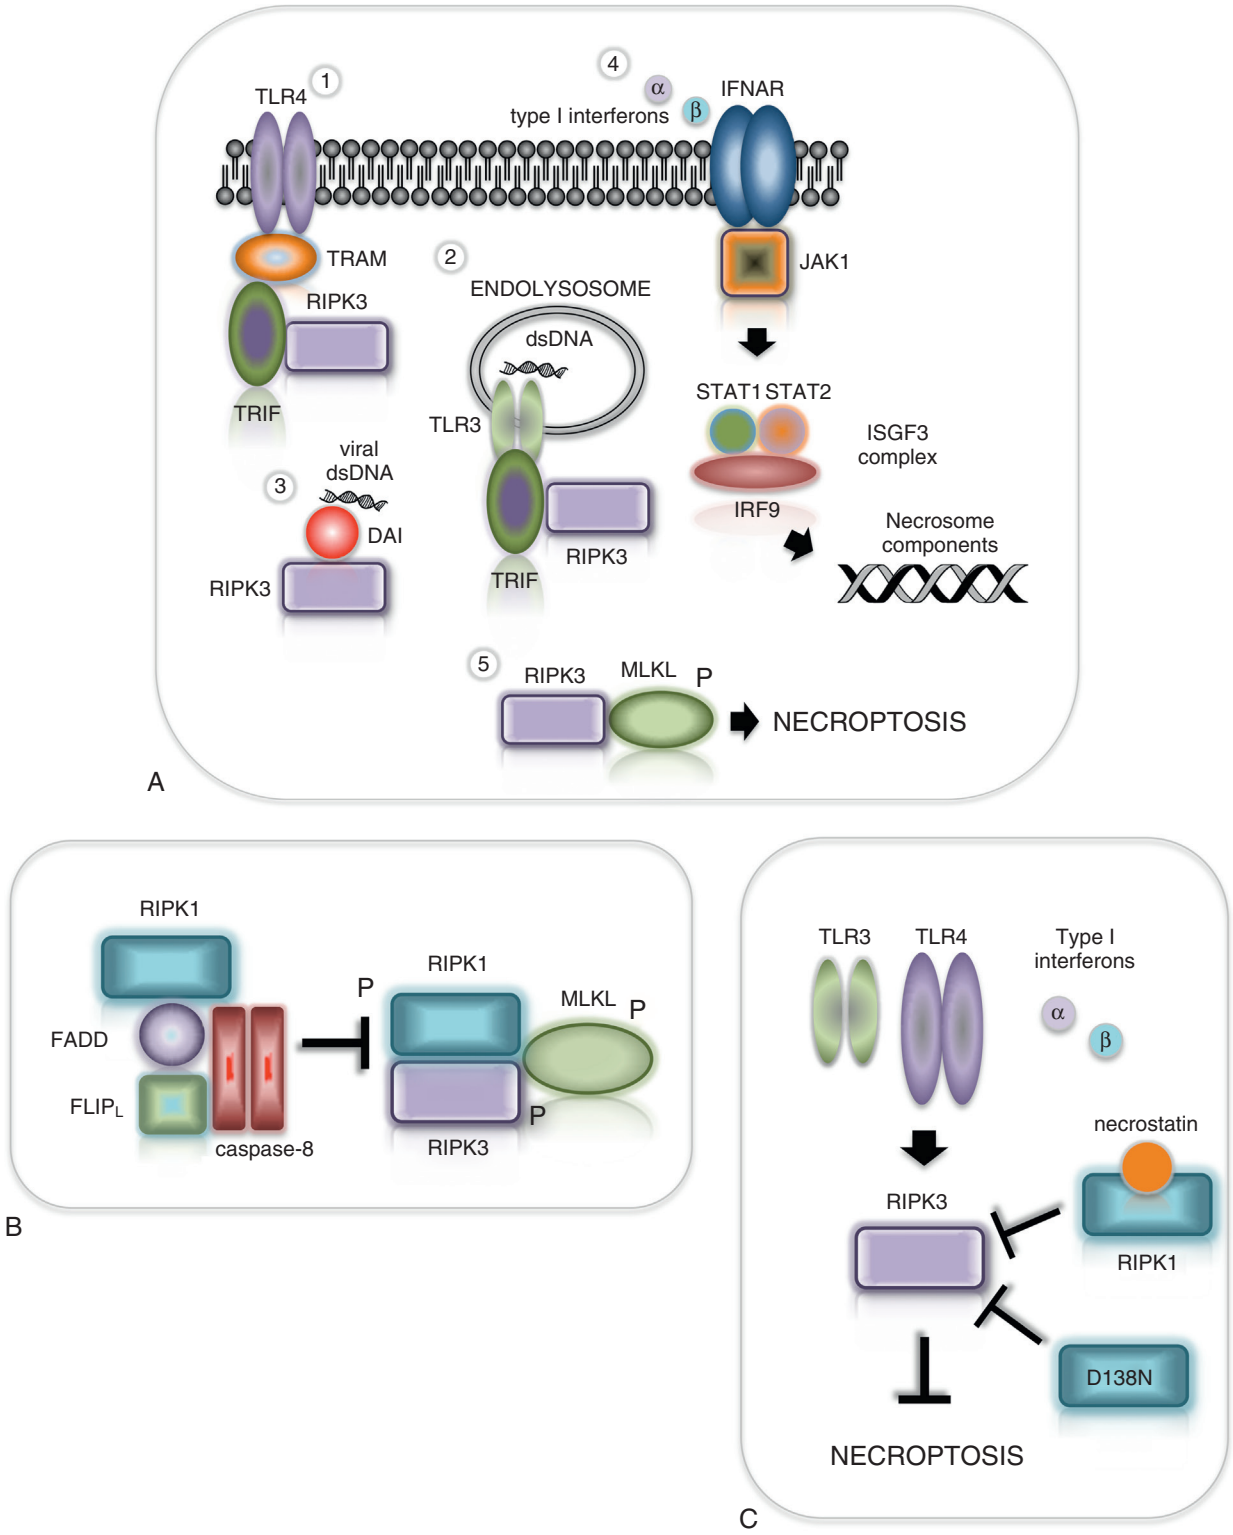

**Figure 28-4** "Signal 2"–dependent necroptosis. **A,** Necroptosis can be engaged in a receptor-interacting protein kinase 1 (RIPK1)-independent manner in response to Toll-like receptor 4 (TLR4) (1), TLR3 (2), DNA-dependent activator of IFN-regulatory factor (DAI) (3), and type I interferons (4). Each of these pathways result in RIPK3-dependent recruitment and activation of mixed lineage kinase domain-like (MLKL) to promote necroptosis (5). RIPK1 can actively suppress RIPK3 via two pathways, shown in **B** and **C**. **B,** RIPK1–death domain (DD) interacts with FAS-associated protein with death domain (FADD)-DD to recruit FLICE-like inhibitory protein long form ($FLIP_L$) and caspase-8, resulting in the inhibition of caspase-8–induced apoptosis, but with retention of sufficient caspase-8 activity to cleave and inactivate RIPK1 and RIPK3 to disrupt the MLKL-activating complex. **C,** Alternatively, kinase inactive RIPK1 or its inhibition by necrostatin also suppress TLR-induced necroptosis. Therefore, kinase inactive RIPK1 can block RIPK3-MLKL–dependent necroptosis. dsDNA, Double-stranded DNA; dsRNA, double-stranded RNA; IRF9, interferon regulatory factor 9; ISGF3, interferon-stimulated gene factor 3; STAT, signal transducer and activator of transcription; TRAM, translocation-associated membrane; TRIF, TIR-domain–containing adapter-inducing interferon-β. *(From Weinlich R, Green DR: The two faces of receptor interacting protein kinase-1.* Mol Cell *56:469–480, 2014, and Pasparakis M, Vandenabeele P: Necroptosis and its role in inflammation.* Nature *517:311–320, 2015.)*

signaling events under a variety of physiologic conditions and to determine if the inhibition of necroptosis may be therapeutically advantageous.[253] The realization, however, that RIPK1 function is dispensable for RIPK3-MLKL–dependent necroptosis under certain conditions should be factored into any conclusion that relies solely on the use of necrostatin. Nonetheless, in several models that mimic a variety of pathophysiologic conditions, including ischemic brain injury, myocardial infarction, and kidney ischemia-reperfusion injury, necrostatin was shown to provide significant projection against tissue damage and, in some cases, offset detrimental immune cell infiltration.[189]

The mechanism(s) by which necroptosis triggers inflammation has/have yet to be fully defined but likely involve(s) the associated release of DAMPs to trigger a myriad of inflammatory signaling events[254] or act indirectly by compromising the integrity of epithelial barriers in tissues such as the skin or gut.[255] Perhaps more intriguingly, however, is the recent delineation of RIPK-3–dependent pro-inflammatory pathways that proceed in the absence of necroptosis.[119,122]

## AUTOPHAGY

Autophagy is a cellular garbage disposal mechanism that is engaged in response to multiple stresses including protein aggregation, metabolic dysfunction, and cancer chemotherapeutics to induce degradation of long-lived proteins and damaged organelles. Three distinct pathways can mediate autophagic degradation: microautophagy, chaperone-mediated autophagy, and that most commonly described and discussed here, macroautophagy (herein, "autophagy" will be used to mean macroautophagy). Autophagy is largely regarded as a catabolic survival mechanism that is initiated during periods of stress, such as nutrient deprivation, to generate an alternative intra-cellular energy source and maintain bioenergetic balance. However, autophagy-induced cell death (ACD) is now emerging as a bona fide pathway, triggered by excessive activation of the pathway.[256-259] Autophagy is associated with several diseases including type II diabetes, neurodegeneration, and Chiron's disease, rendering it an attractive target for potential clinical intervention.[260] As we learn more about the underlying mechanisms of autophagy, it is becoming apparent that one of its primary roles is in the context of immune function and that numerous immunoregulatory events intersect with the autophagy signaling network to provide protection against disease and microbial infection.[261,262]

### Molecular Mechanisms of Autophagy

The process of autophagy, in general terms, comprises the inclusion of cytosolic components within the phagophore or isolation membrane, which then matures into a double membrane–bound vesicle, termed the *autophagosome*. The source of lipids to generate the double membrane remains somewhat obscure but likely arises from multiple sources, including the ER membrane. The autophagosome then fuses with lysosomes or endosomes to generate the autolysosome, in which digestion of the vesicular cargo proceeds to generate macromolecules for reuse in cellular metabolic processes. The molecular details of autophagy are complex but for the most part are fairly well characterized (Figure 28-5A, B). The extensive family of autophagy-related genes (ATGs) includes those constituting the critical core machinery necessary for assembly of the autophagosome—the ATG1/UNC51-like kinase (ULK) complex; the ATG12 and ATG8 (LC3) conjugation system; the class III phosphatidylinositol-3-kinase (PI3K)/VPS34 complex; and the transmembrane proteins ATG9 and vacuole membrane protein 1 (VMP1).

This multistep ATG-dependent autophagic process is under the master control of the mammalian target of rapamycin (mTOR) complex.[263,264] mTOR, a serine-threonine kinase, is responsive to growth factor signaling, changes in nutrient availability, and energy status. It functions within the RAPTOR-containing mTORC1 complex[265] to integrate signals arising from the AKT pathway under conditions of nutrient availability to suppress autophagy.[264] However, when nutrients are limited, mTOR activity is inhibited and the autophagic process is initiated. The downstream mediator of mTOR activity is the ULK complex, comprising several proteins that are required for autophagosome formation.[266,267] In mammals, there are three ULK members, ULK1, ULK2, and ULK3, all of which are reportedly involved in the autophagic pathway. However, it remains unclear whether their respective roles differ mechanistically and/or are associated with different stress-inducing stimuli and/or cell type.[259] ULK1 and ULK2 are part of a large complex containing ATG13 and the scaffold protein FIP200.[266-268] Importantly, although this complex is assembled independently of nutrient availability, it is regulated in a nutrient-dependent manner. Nutrient sufficiency stimulates the incorporation of mTORC1 into the ULK1 complex to facilitate mTOR-mediated phosphorylation and inhibition of ULK1, ULK2, and ATG13. However, under conditions of starvation, leucine deprivation, and/or rapamycin-mediated suppression of mTOR, mTORC2 dissociates from the complex and the activity of ULK1 and -2 is regained, resulting in the phosphorylation of FIP200 and ULK1 in a ULK1-dependent manner.[266,267]

Beclin-1 (Bcl-2 interacting coiled coil protein) (mATG6) is essential for mammalian autophagy[269] and forms three independent complexes that collectively regulate the next phase of autophagy to generate the mature autophagosome. These three complexes comprise (1) Beclin-1, VPS34 (a PI3K that generates phosphatidylinositol triphosphate [$PIP_3$]), VPS15, and ATG14L; (2) Beclin-1, VPS34, VPS15, and ultraviolet irradiation resistance-associated gene (UVRAG); and (3) Beclin-1, VPS34, VPS15, UVRAG, and Rubicon (RUN domain and cysteine-rich domain containing Beclin 1–interacting protein).[270,271] The first complex initiates autophagy and is thought to generate the requisite $PIP_3$ and "mark" the phagophore membrane for the subsequent recruitment of additional ATG proteins, such as ATG16L and LC3. UVRAG, a component of the second complex, competes with ATG14L for binding to Beclin-1 to promote autophagosome formation via the stimulation of VPS34 activity. Rubicon opposes this activity by direct interaction with VPS34 to suppress $PIP_3$ generation and autophagosome assembly.

After initiation of phagophore formation by the VPS34-Beclin-1 complex, expansion of the vesicular membrane is completed by two ubiquitination-like conjugation

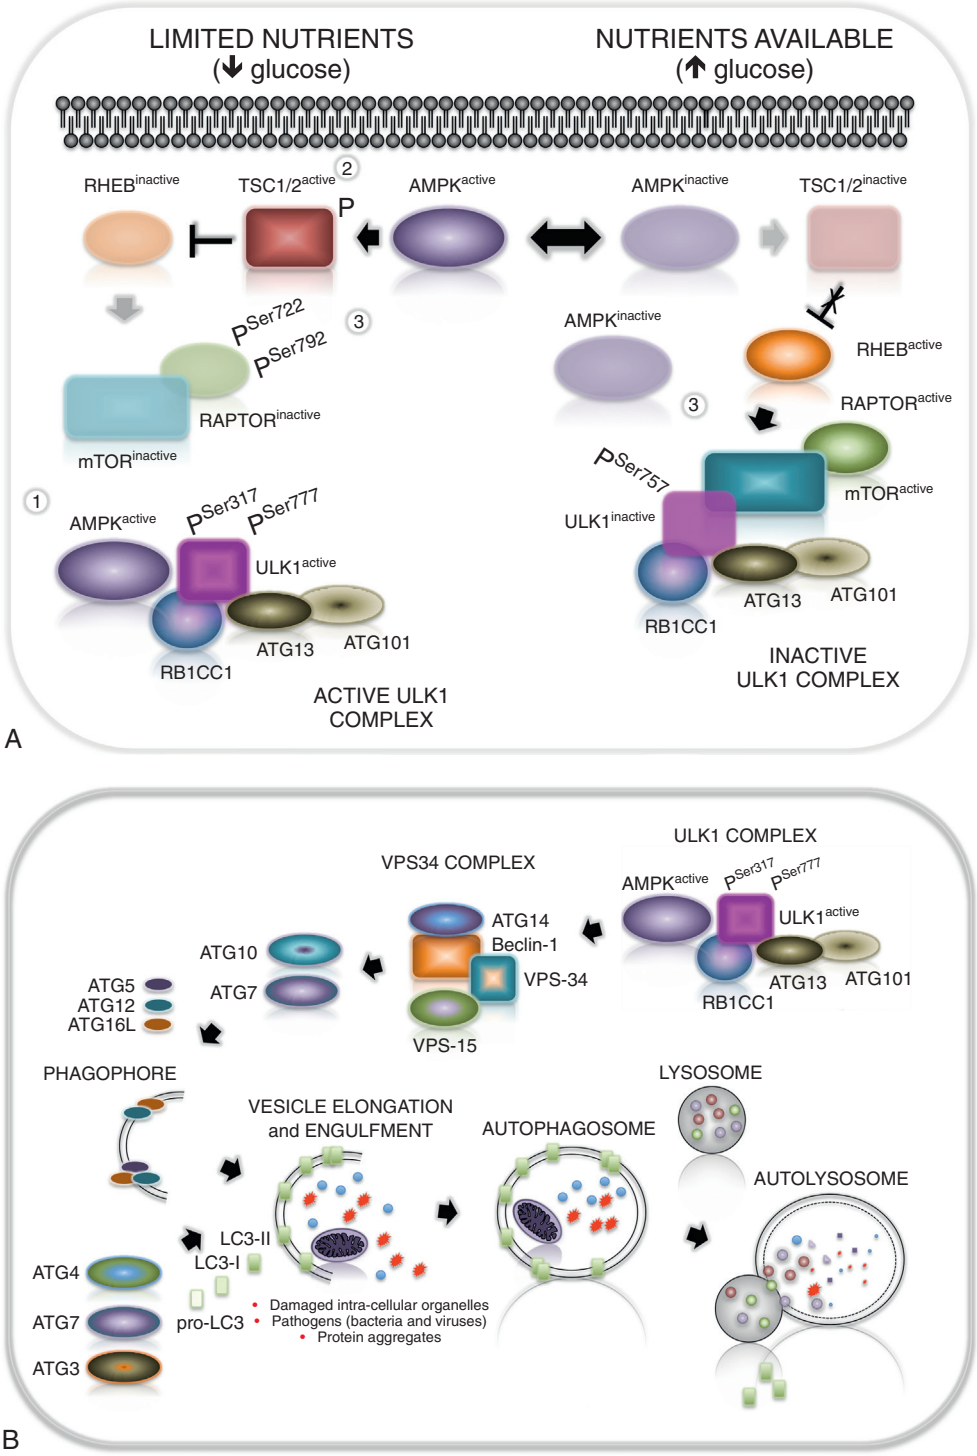

**Figure 28-5** Autophagy is engaged by multiple stresses including protein aggregates, intra-cellular pathogens, metabolic dysfunction, and cancer chemotherapeutics to induce degradation of long-lived proteins and damaged organelles. **A,** Upstream signaling: The mammalian target of rapamycin (mTOR) and UNC51-like kinase (ULK) complexes function in an opposing manner, with mTOR acting to inhibit autophagy and the ULK complex acting to initiate it. During times of glucose restriction or other stresses, adenosine monophosphate-activated protein kinase (AMPK) phosphorylates and activates ULK1 (Ser317 and Ser777) (1) to initiate assembly of the ULK complex comprising ULK1, autophagy-related gene (ATG)13, ATG101, and RB1CC1 (or FIP200). This complex is critical for the initiation of autophagy. AMPK negatively regulates the mTOR pathway by phosphorylating both tuberous sclerosis (TSC) (2) to inhibit Ras homolog enriched in brain (RHEB) and RAPTOR (Ser722 and Ser792) (3), a protein necessary for mTOR activity. Conversely, under conditions of nutrient sufficiency, AMPK activity is suppressed, TSC is rendered inactive, and RHEB, now active, phosphorylates ULK1 (Ser757) to disrupt its interaction with AMPK and activates mTOR. **B,** Downstream events: Activation of the ULK complex in response to stresses such as nutrient deprivation initiates assembly of the phosphatidylinositol 3 (PI3) kinase VPS34 complex, which in turn generates PI3P, an important component of the autophagosome membrane. The initiator membrane or phagophore, the precise source of which remains unclear, is then decorated with the ATG5-ATG12-ATG16L complex together with lipidated LC3 (LC3-II) via the combined activities of two ATG conjugation complexes—ATG10 and -7 and ATG3, -4, and -7. The double membrane then undergoes elongation to encapsulate the cargo destined for disposal including pathogens, dysfunctional organelles, and large insoluble protein aggregates. This action forms the autophagosome, which fuses with a lysosome to form the autolysosome. The lysosomal proteases then mediate proteolytic destruction of the cargo, thereby inactivating pathogens and/or providing nutrients for recycling and restoration of bioenergetic potential during conditions of limited nutrient availability. *(From Yang Z, Klionsky DJ: Mammalian autophagy: core molecular machinery and signaling regulation.* Curr Opin Cell Biol *22:124–131, 2010.)*

pathways, both of which require the E1 ligase activity of ATG7. In one, the small protein ATG12 is conjugated to ATG5 using ATG7 and ATG10 as the E1 and E2 ligases, respectively. The ATG5-ATG12 conjugate then interacts with ATG16L to form a large complex. In the second pathway, pro-LC3 is first cleaved by ATG4 to generate cytosolic LC-1, which is then conjugated to the lipid, phosphatidylethanolamine, using ATG7 and ATG3 as the E2 ligase. The lipidated form of LC3, LC3-II, is inserted in the autophagosomal membrane. Although the conversion of LC-I to its lipidated LC3-II form is commonly used as a marker for autophagy, LC3-associated phagocytosis (LAP), a process that shares common signaling components with autophagy, is also characterized by the formation of membrane-bound vesicles decorated with LC3-II.[272] Fusion of the mature LC3-II$^+$ autophagosome with lysosomes to form autolysosomes then initiates proteolysis and digestion of the vesicular cargo.

The biologic significance of autophagy is evident in the context of tumor growth. Heterozygous deletion of Beclin-1/ATG6 promotes tumor formation in several murine models, and monoallelic loss in several human tumor types is also frequently observed. Furthermore, several Beclin-1-interacting proteins have been implicated in tumorigenesis and the regulation of proliferation including BIF-1 or Endophilin B1, AMBRA or activating molecule in beclin-regulated autophagy, and BCL-2. The role for Beclin-1 and autophagy in tumor suppression presumably reflects its ability to effectively remove potentially toxic protein aggregates and dysfunctional organelles to limit the harmful consequences of ROS production and genomic lesions. However, cell death is also a potent tumor suppressor mechanism, as evidenced by the pro- or antitumorigenic activities of numerous regulators of apoptosis, including BCL-2 and p53. It is therefore conceivable that the tumor suppressive activity of Beclin-1 may instead reflect its role in promoting autophagic cell death.

However, a direct role for autophagy in promoting cell death has proven difficult to substantiate. Historically, delineation between the detection of autophagic markers arising as a consequence of or coincidentally with the destruction of dead cells and cell death arising directly from autophagy-generated signals has confounded the unambiguous identification of ACD. However, the availability of genetic tools has now provided definitive characterization of a form of autophagic cell death that can be triggered by overactivation of the autophagy pathway. Accordingly, under some circumstances, the deletion of one more component of the autophagy pathway is sufficient to inhibit cell death—a criterion that must be applied to determine the authenticity of cell death driven by autophagy.

## Overeating Is Good for You—Autophagy and the Immune System

Autophagy regulation via NLRs—that is, inhibition of inflammasome formation via deletion of some NLRs—can promote autophagy, suggesting that the inflammasome may negatively regulate autophagy, or perhaps that suppression of pyroptosis engages autophagy to promote an alternative type of cell death. Conversely, evidence suggests that autophagy inhibits the inflammasome and that defects or polymorphisms in autophagy are associated with inflammatory disease. For example, systemic lupus erythematosus and Crohn's disease are associated with polymorphisms in *Atg5* and *Atg16*, respectively.

## Mitophagy

Mitophagy is a specialized autophagic process that deletes dysfunctional organelles to maintain overall mitochondrial integrity and to provide the necessary components for mitochondrial regeneration. The removal of damaged mitochondria is mediated by their selective targeting to the LC3$^+$ phagophore to promote engulfment and degradation by the autophagosome. Mitochondrial effector proteins can initiate one of two mitophagy pathways—ubiquitin- or receptor-mediated—triggered by ubiquitin-tagged proteins or those containing LC3-interacting regions (LIRs), respectively.

The outer mitochondrial membrane LIR-containing proteins, NIX1, also known as BNIP3L, BNIP3 (BCL-2 and adenovirus E1B 19-kDa-interacting protein 3), and FUNDC1 (FUN14 domain containing 1), trigger mitophagy under different physiologic conditions. NIX1, for example, mediates mitochondrial removal in the reticulocyte, which is a critical step during the development of mature erythrocytes, whereas both BNIP3 and FUNDC1 are important for the removal of mitochondria as a consequence of hypoxia. Serine phosphorylation adjacent to the LIR domain of BNIP3 and dephosphorylation/phosphorylation of FUNDC1 regulate their interaction with LC3 under conditions of reduced oxygen. Externalization of cardiolipin, normally localized on the inner mitochondrial membrane, also facilitates binding to LC3 and the removal of damaged mitochondria in neuronal cells.

Ubiquitin-dependent mitophagy is mediated by the coordinated activities of the serine-threonine kinase PTEN-induced putative kinase 1 (PINK1) and Parkin, an E3 ligase. Accumulation of PINK1 on the outer surface of mitochondria triggers the kinase-dependent recruitment and activation of Parkin to promote the attachment of ubiquitin to several proteins within the outer mitochondrial membrane (OMM). The constitutive turnover of PINK1 prevents the inappropriate deletion of mitochondria and is regulated by transporter outer membrane (TOM)-dependent translocation to the inner mitochondrial membrane and proteolysis by the rhomboid protease, presenilins-associated rhomboid-like protease (PARL). However, upon loss of outer membrane potential or in response to the accumulation of excess unfolded proteins in the mitochondrial matrix, the import of PINK1 is inhibited, proteolysis is prevented, and instead it accumulates on the surface of the mitochondria. PINK1-mediated phosphorylation of a serine residue within both the ubiquitin domain of Parkin and ubiquitin itself triggers a conformational change in Parkin and acquisition of its E3 ligase activity. Parkin-mediated Lysine 48–linked ubiquitination of several substrates, including the fusion proteins mitofusin-1/mitofusin-2, encoded by the *Mfn1/Mfn2* genes, promotes their degradation to facilitate mitophagy. A number of additional accessory proteins appear to be critical for Parkin-mediated mitophagy, although their precise roles remain unclear. These include several additional Parkin substrates and

the autophagy adapter proteins ULK1, ATG14, and ATG16L1, all of which translocate to mitochondria during mitophagy.

The physiologic significance of ubiquitin-mediated autophagy is exemplified by the frequent mutation of PINK and Parkin and accompanying mitochondrial dysfunction in certain autosomal recessive forms of Parkinson's disease. Mitophagy also shares many signaling components with xenophagy, an autophagy-dependent process that mediates the destruction of intra-cellular bacteria. Indeed, Parkin has been implicated in the ubiquitination and clearance of *Mycobacterium tuberculosis* and in the susceptibility of mice and *Drosophila* to several intra-cellular infections. Intriguingly, polymorphisms in the human Parkin gene, *PARK2*, correlate with an increase in susceptibility to *Mycobacterium leprae* and *Salmonella enterica*.

## Mitophagy and Immune Function

The role of mitochondria in various types of cell death clearly has implications in immune regulation. However, additional mitochondria-dependent activities, including their role in MAVS-mediated signaling and as a source of DAMPs such as ROS and mitochondrial DNA underscore the importance of mitochondrial integrity and the role of mitophagy in innate immune responses.

Clearly, sustaining mitochondrial function is essential not only for maintaining oxidative phosphorylation, a critical source of ATP, but also for regulating cellular oxidation via ROS production. Damaged mitochondria are a rich source of ROS, requiring efficient removal by mitophagy to limit potential oxidative damage. Mitochondria-mediated ROS production as a consequence of defective mitophagy and accumulation of damaged mitochondria is a potent mediator of NLRP3-dependent inflammasome activation and IL-1β production. RIPK2-dependent phosphorylation of ULK1 to promote mitophagy similarly limits aberrant NALP3 inflammasome assembly and inflammation during viral infection. Effective anti-viral immunity also includes a role for the mitochondria-localized MAVS, an adapter protein that promotes inflammation in a RIG-1–dependent manner. Negative regulators of MAVS signaling include the ubiquitin ligases, SMURF1 (SMAD ubiquitination regulatory factor 1), MUL1 (mitochondrial ubiquitin ligase 1), and Gp78, all of which have been implicated in the regulation of mitophagy. Furthermore, dissipation of mitochondrial membrane potential severely limits MAVS-mediated signaling. Maintaining mitochondrial fidelity is therefore an essential component of immune regulation.

## "Like All Successful Relationships, It's Complex"—Interaction between Cell Death and Immune Function

A complementary relationship between the immune system and cell death exists. As we have discussed at points throughout this chapter, components of inflammatory responses, such as TNF and IL-1β, can induce cell death and, in a reciprocal manner, dead or dying cells can have a significant impact on immune function. Cell death plays critical roles in development of the immune system, maintenance of normal homeostasis, and in regulating immune function in response to pathogenic invasion. However, the specific type of cell death, how it is induced, and the signaling and molecular events associated with it can differentially alter the inflammatory response.

TLRs and NLRs are vital for the detection pathogens by responding to PAMPs, pathogen-derived components that trigger TLR and NLR signaling events to engage inflammation. At the heart of these responses in most cases is the inflammatory caspase, caspase-1, which is activated by inflammasome assembly to cleave, activate, and secrete IL-1β and IL-18. The efficiency with which this pathway can detect, respond, and eliminate pathogens is matched only by the equally effective mechanisms expressed by pathogens to subvert detection, disrupt critical pro-inflammatory signals, and evade elimination. Pathogens are master manipulators, evolved to avail of beneficial host-derived pathways and to disrupt the mechanisms detrimental to their replication and survival. It is therefore no surprise that both viruses and bacteria have evolved multiple ingenious mechanisms to evade host-mediated elimination by expressing proteins that regulate components of the apoptotic and necroptotic signaling machinery.

Caspase-1 is at the epicenter of inflammatory responses and host immune defense by virtue of its ability to cleave and activate pro-IL-18 and pro-IL-1β, both of which have diverse roles in immune regulation and protection against bacterial and viral infection. It is therefore no surprise that pathogens have evolved to express multiple virulence factors able to disrupt inflammasome assembly and/or its downstream pro-inflammatory effects (reviewed in references 273-275).[273-275] A few examples are provided.

Poxvirus family members express one of several so-called "serpins," including cowpox virus protein cytokine response modifier A (CRMA), SPI-1, and SPI-2 that directly inhibit the enzymatic activity of caspase-1 and caspase-8.[276-278] CRMA acts as a pseudosubstrate for caspase-1, forming a covalent bond with the active site cysteine in caspase-1 to render it catalytically inert.[279,280] Additional mechanisms through which virulence factors can disrupt the pro-inflammatory activity of inflammasomes include the secretion of soluble scavenger proteins that neutralize host-derived cytokines such as an IL-1β receptor able to bind to and inactivate host-derived IL-1β[281] and soluble IL-18 inhibitory binding proteins to neutralize host-derived IL-18.[282] Several virulence factors can also directly disrupt inflammasome formation, primarily by the expression of decoy proteins. Examples include the herpes virus–derived protein, Orf63, an NLRP1 homolog that lacks both the CARD and pyrin interaction motifs that, by associating with host NLRP1 or NLRP3, prevents caspase-1 recruitment and activation.[283] Virally derived POPs also act as decoys to sequester PYD-containing host proteins involved in inflammasome assembly, including the adapter protein ASC.[284,285]

Bacterial factors that function to dysregulate the inflammasome–IL-1β/IL-18 axis include the *Yersinia* Yop proteins, negative regulators of Rho guanosine triphosphatases that inhibit caspase-1 activation[286] and mask recognition by the NLRs, NLRP3 and NLRC4, to prevent inflammasome assembly.[287] Several other bacterial-derived proteins with a diverse array of activities negatively regulate the assembly of different types of inflammasome or directly inhibit caspase-1 activity, although the precise mechanisms

mediating these effects remain unclear. Examples of these proteins include ExoU, a protein that harbors phospholipase A2 activity, the ADP-ribosyl transferase, ExoS,[288,289] Zmp1, a $Zn^{2+}$ metalloprotease, and the lipid flippase *mviN*.

Apoptotic caspases orchestrate the demise of a cell and therefore by definition would appear as very vulnerable targets to those unscrupulous pathogens intent on survival. As we have already discussed, mammalian cells also express their own caspase inhibitor, XIAP. But so too do pathogens—in fact, the first IAP to be identified was isolated from baculoviruses and provided the basis for their subsequent identification in vertebrates based on BIR domain homology. CRMA, expressed by pox viruses and a potent inhibitor of caspase-1 function (previously discussed) can also inhibit the catalytic activity of caspase-8 function. Baculovirus also expresses p35 protein, which, once cleaved and processed, functions as a pseudosubstrate for caspases, thereby binding to and inhibiting the catalytically active cysteine and preventing proteolysis of target substrates.

Herpes viruses, including murine cytomegalovirus (MCMV), can circumvent death of the infected host cell by expressing the viral inhibitor of caspase-8 processing (vICA). Clearly, although this activity may effectively suppress caspase-8–dependent apoptosis and limit viral replication, it coincidentally triggers necroptosis–an alternative cell death pathway that also has a critical role in anti-viral immunity. However, cells infected by MCMV neither succumb to apoptosis nor necroptosis because it also expresses the RHIM-like domain containing protein, vIRA, product of the *M45* gene that prevents interaction between RIPK3 and DAI, a sensor of viral infection. The viral protease NS3/4a binds to mitochondria where it cleaves an important signaling adapter, MAVS, thus preventing viral clearance by endogenous IFN production. Viral infection also triggers TNF production as part of the host defense mechanism to induce necroptosis. Both $Ripk1^{-/-}$ and $Ripk3^{-/-}$ cells are refractive to TNF-induced programmed necrosis as evidenced by abrogation of necrosis and inflammation in mice deficient for RIPK3. However, the failure to induce necroptosis manifests as uncontrolled viral replication, an inability to clear infection, and, ultimately, death of the host. Thus it is possible that necroptosis may act as a form of defense against viral infection.

Bacteria have also evolved multiple mechanisms to regulate cell death and inflammatory pathways, both of which can be detrimental to their survival (reviewed in references 274 and 275). TNF-induced signaling is frequently targeted by components of pathogenic bacteria to prevent bacterial elimination induced by either TNF-induced inflammation or cell death. Cell death also serves as a rich source of PAMPS to trigger inflammation and limit bacterial replication. NF-κB, a component of TNF-induced signaling, is a critical regulator of inflammation via the transcriptional induction of several cytokines. NleB and various homologs, expressed by *Salmonella* and other pathogenic *E. coli* strains, are potent inhibitors of TNF-induced NF-κB activation. Several mechanisms exist, including that mediated by the unusual ability of NleB proteins to modify arginine residues via N-acetylglucosamine transferase activity. Strikingly, NleB can modify a highly conserved arginine residue critical for intermolecular interactions in the DD of multiple components of TNF-induced signaling, including TRADD, FADD, TNFR1, RIPK1, FAS/CD95, DR3, and the TRAIL receptors.[290] Translocated-intimin receptor (Tir), a bacterial protein characterized by ITIM-like motifs (immunoreceptor tyrosine-based inhibition motifs), is also an effective inhibitor of NF-κB. Although the precise mechanism by which this process is mediated remains unclear in mammalian cells, ITIMs are present in the cytoplasmic signaling domains of the T cell and B cell receptors and function to negatively regulate proimmune signaling events and limit effector function, suggesting that bacterial Tir may function in an analogous manner.

As we have discussed, ubiquitylation of several components of the TNF-R-signaling complex can profoundly alter biologic outcome and determine if a cell lives or dies. Accordingly, several mechanisms by which bacterial proteins can disrupt ubiquitylation events to alter the stability of signaling intermediates in the TNF-R complex have also been identified. For example, NleE and related proteins in several bacteria, including *Shigella* and *Salmonella*, function to modify critical cysteine residues in proteins necessary for the coordination of ubiquitylation events required for NF-κB activation. Other bacterial proteins can disrupt NF-κB activation by inhibiting the degradation of IκB, either by directly interacting with ubiquitin conjugates or by targeting NEMO for proteasomal destruction. The subunits of NF-κB, p65, and p50 can also be directly cleaved and inactivated by a bacterial zinc metalloprotease NleC.[291]

As previously discussed, hetero- and homodimerization of pro- and anti-apoptotic BCL-2 proteins regulate mitochondrial events, specifically MOMP, that are required for the activation of caspase-9 to promote or suppress apoptosis. As we might predict, the significance of this event does not escape the wily virus. To that end, several viral BCL-2 proteins have been identified that function to mimic many of the activities of mammalian prosurvival proteins to neutralize the effector function of BAX and BAK and maintain cellular survival. Although in many cases v-BCL-2 proteins display very limited sequence homology to their mammalian orthologs, by virtue of their structural plasticity and ability to adopt the conformations required to mimic BCL-2 function, they are able to disrupt the function of proapoptotic BCL-2 proteins via association with the effector molecules BAX and BAK to inhibit their MOMP-inducing activity or, alternatively, associate with and sequester the BH3-only proteins. Although v-BCL-2 proteins can effectively inhibit cell death, the affinity for proapoptotic proteins is much reduced compared with mammalian BCL-2. It is intriguing to speculate that perhaps the "suboptimal" performance of v-BCL-2 proteins may be supplemented by their abilities to regulate additional signaling pathways important for cell death induction. Indeed, recent evidence suggests that the vaccinia BCL-2 ortholog, F1L, can both inhibit caspase-9 activity and disrupt inflammasome assembly. With much to learn about the function of mammalian BCL-2 proteins, it remains only a matter of time before new findings instruct our understanding of v-BCL-2 proteins or, as is often the case, viruses teach us something new.

## CONCLUSION

As we uncover the molecular characteristics and regulatory components of different cell death pathways and their

relevance to specific physiologic scenarios, the more likely it is that pharmacologic intervention may be utilized to recover normal function under pathophysiologic conditions. To that end, several pharmacologic regulators of cell death are currently under development and/or in the clinic for their potential application to a range of pathologies, including those characterized by aberrant cell death and immune dysfunction.

## Caspase Inhibitors

Currently, no caspase inhibitors are in clinical trials. Several pharmacologic inhibitors used experimentally include the peptide-based inhibitors z-VAD-fmk and qVD-oph, and the small molecule inhibitor, IDN-6556.

## Necroptosis Inhibitors

The role of the RIP kinases in necroptosis has prompted the search for inhibitors of these kinases. The RIPK1 inhibitor Necrostatin-1, widely used experimentally, also inhibits the enzyme IDO, which has immunologic consequences. Another RIPK1 inhibitor, Necrostatin-1s, does not have this cross-reactivity. RIPK3 inhibitors are also described, including GSK2399872B. Necroptosis can also be inhibited by targeting MLKL. Necrosulfonamide inhibits human but not murine MLKL, and as yet, no rodent inhibitors have been identified. Currently, no inhibitors of necroptosis are approved for human use.

## BH3 Mimetics and BCL-2/MCL-1 Inhibitors

Several inhibitors of anti-apoptotic BCL-2 proteins are described, including Obatoclax (GX15-070), Gossypol (AT-101), a natural phenolic compound and the Gossypol derivative, Sabutoclax (ONT-701). However, none of these agents have been shown to have specificity for their targets. Of more potential utility are the BH3 mimetic compounds, which include the experimental compounds ABT-737 (inhibitor of BCL-$X_L$, BCL-2, and BCL-w), WEHI-539 (a BCL-$X_L$ selective inhibitor), and UMI-77 (an MCL-1 selective inhibitor) and the drugs navitoclax (ABT-263) (inhibitor of BCL-$X_L$, BCL-2, and BCL-w), venetoclax (ABT-199) (a BCL-2 selective inhibitor), and A-1155463 (a BCL-$X_L$ selective inhibitor). The BH3 mimetics show exquisite specificity for the anti-apoptotic Bcl-2 proteins and are in clinical trials for a number of human malignancies.

## IAP Inhibitors

As previously discussed, ubiquitination is a powerful modulator of multiple pathways, including the TNFR1 signaling complex, to regulate the selective engagement of cellular survival or the death pathways, apoptosis and necroptosis. These include the NF-κB inhibitory complex IκB to induce its degradation, thereby promoting NF-κB transcriptional activation. RIPK1 is also regulated by IAP-mediated ubiquitination, and it is this activity that helps to divert TNFR1-mediated signaling toward survival by accelerating RIPK turnover. The use of SMAC mimetics (SMs), which function as antagonists of IAP function and promote the auto-ubiquitination and degradation of IAPs, can overcome cellular survival and increase the sensitivity of cells to RIPK-mediated necrosis. This approach could be of clinical importance by circumventing the commonly observed resistance of cancer cells to apoptotic death and instead evoke death in an RIPK-dependent manner. As we begin to understand how RIPK-mediated death may intersect with immune function, it may also be possible to utilize SMs to prime immune function against tumor-derived antigens. Harnessing or unleashing the hosts' own defense mechanism via activation of the immune system to directly target tumor cells, which are often able to evade immune detection, is an approach receiving an enormous amount of focus. It would seem feasible to suggest that tumor cells, frequently characterized by mutation and inactivation of apoptotic pathways, may be rendered susceptible to SMAC-mediated sensitization to induce programmed necrosis, in the hope that the associated activation of immune function will further exacerbate tumor regression.

## Autophagy Regulators

Autophagy is negatively regulated by TORC1, and therefore TORC1 inhibitors are an effective way to engage autophagy in cells under nutrient-replete conditions. The inhibition of the final step of lysosomal degradation can be inhibited by chloroquine and related compounds, and the combined use of TORC1 inhibitors and chloroquine has been investigated as therapeutics for human malignancies. Inhibition of the earlier steps in autophagy has not been reported, although broad PI3K inhibitors, including Wortmannin and 3-methyladenosine, can inhibit canonical autophagy. Effective inhibition of autophagy by such treatments as a means to disrupt autophagic cell death has not shown promise, however.

CHAPTER 29

# Experimental Models for Rheumatoid Arthritis

Rikard Holmdahl

**KEY POINTS**

- **Animal models are tools to understand the basic mechanisms believed to cause rheumatoid arthritis (RA).**
- **Many different animal models exist for RA, some of which are standard, such as collagen-induced arthritis (CIA), collagen antibody–induced arthritis (CAIA), and adjuvant (pristane)-induced arthritis (PIA).**
- **Arthritis can be induced in animals by immunization with cartilage components, adjuvants, bacterial or viral components, or genetic modification.**
- **Animal models have a defined disease course and are useful for analysis of the three stages that lead to RA: priming, onset, and chronicity.**
- **Animal models allow controlled experiments with specific variations of environment and genetics.**
- **Animal models provide direction for novel approaches to treatment, such as cytokine inhibition.**

For a deeper understanding of the complexity of the pathogenesis of rheumatoid arthritis (RA), the use of animal models is a necessity. Obviously, a disease identical to RA in humans cannot develop in animals because they are of different species with different genetics and environments.

The three main advantages of using animal models are as follows:

- Inbred animal strains can be genetically and environmentally controlled.
- Manipulative experiments can be performed. The genome of inbred strains can be changed by mutations, insertions, and deletions. The environment can also be changed in a controlled way; they can be immunized or infected which may lead to arthritis. Controlled experiments can be performed.
- It is more ethical to use animals instead of humans.

To evaluate and select proper animal models for RA, it is of value to reproduce some of the basic features of RA. The following are hallmarks of RA.

- *The disease starts before the clinical diagnosis*. An autoimmune and inflammatory process precedes the clinical onset by several years.
- *Tissue-specificity*. RA is characterized by a tissue-specific inflammatory attack affecting diarthrodial, peripheral, and cartilaginous joints. Although systemic immune responses as well as manifestations are usually present, the inflammation is mainly directed towards peripheral joints.
- *Chronicity*. The disease is chronic and occurs in tissues in which no causative infectious pathogens have so far been demonstrated. Acute joint affections are common manifestations in both physiologic responses to infections and in connection with other inflammatory disorders, but in RA chronicity is an essential characteristic. The disease course may proceed with identifiable relapses, but there is usually a steady progression of joint destruction.
- *Autoantibodies*. The development of RA is preceded and associated with elevated levels of autoantibodies in serum. Anti-citrullinated protein antibodies (ACPA) have the highest specificity and sensitivity followed by antibodies to immunoglobulin (rheumatoid factors), but antibodies to other antigens do also occur in subsets of patients, such as antibodies to type II collagen (CII) and to hnRNP-A2.
- *Class II major histocompatibility complex (MHC) association*. The genetic influence is significant but complex. The by far largest genetic contributions are class II genes in the major histocompatibility complex. In particular certain structures in the peptide-binding pocket of human leukocyte antigen (HLA)-DR4 molecules are highly associated with RA. Several other loci confirm an involvement of adaptive immunity *(PTPN22, CTLA4, IL21)* strengthen the view that RA is an autoimmune disease.

Accumulating data suggest that RA develops in three discrete stages: priming, onset, and chronicity (Table 29-1). The disease priming process starts several years before clinical onset, with enhanced levels of autoantibodies (ACPA and RF) and a higher level of inflammation markers. Thus, it is likely that the etiologic factors are operating at this early time. Some authors have suggested that smoking and various chronic infections such as periodontitis are associated with the early disease process.[1] This process, however, is not joint specific, and a further spreading of the autoimmune reactivity towards joint structures is likely to occur before the onset of arthritis. To be classified as RA, the first appearance of arthritis needs to progress with chronic inflammation in the joints to establish the disease state that has been extensively described by clinical research. Animal models, however, have not yet been used to describe the established chronic stage but, usually, only the second-onset phase (see Table 29-1).

In all three phases, it has been considered that an infectious agent plays a critical role, but with different mechanisms. In the first priming phase, it is believed that an

**TABLE 29-1** Three Stages of Rheumatoid Arthritis Development in Human and Animal Models

| Disease Stage | Studies in Humans | Studies in Animal Models | Stage-Suitable Models |
|---|---|---|---|
| Pre-RA | Only few retrospective studies | Many studies but not mimicking pre-RA | No models mimicking pre-classic RA with both class II MHC association and ACPA response. The most promising models involve induction of autoimmunity by various adjuvant components. |
| Clinical onset | Only few studies | Most studies | Most models useful. Each model may involve specific pathways leading to subtypes of arthritis. |
| Chronic arthritis | Almost all studies | Almost no studies and only few models | DA rat or C57Bl mouse strains may show chronic relapsing models with adjuvant (pristane) or cartilage/antigen induced arthritis.<br>Several spontaneous arthritis models show chronic progressive arthritis. |

RA develops in three discrete steps, but the focus on the different stages has been different in human RA and animal models.
ACPA, Anti-citrullinated protein antibody; MHC, major histocompatibility complex; RA, rheumatoid arthritis.

infectious agent triggers an inflammatory response involving citrullination that the immune system responds to, such as *Porphyromonas gingivalis* causing chronic gingivitis. In the onset phase, infections of joints can trigger a joint inflammation such as with *Borrelia*, which could persist in the joints and explain the chronic relapsing pattern. Alternatively, the initiating immune reaction could be caused by triggering of chronic inflammation by noninfectious agents that could give rise to citrullination and the breakdown of tolerance to endogenous autoantigens. The inflammatory targeting of the joints, and the chronic relapsing pattern, could also be explained by breakdown of tolerance to joint antigens.

It is likely that the adaptive immune system is critical for the initiation and onset of disease, in particular because these stages seem to be strongly associated with class II MHC and lymphocyte activation genes; whereas no strong evidence exists that the chronic relapsing stage is driven by the adaptive immune system. Chronically activated fibroblasts and, perhaps, macrophages could drive the disease.

Thus the causes and driving forces are not yet clarified and are likely to operate differently in different diseases leading to the syndrome we call *rheumatoid arthritis*.

Animal models are excellent tools for understanding the basic mechanisms of the immune system and how it may develop disease, and disease models are excellent for analysis of distinct pathways and are likely to reflect distinct subsets of human disease. Recent advancement of different animal models mimicking different aspects of human diseases as well as the improvement in genetic techniques has dramatically increased their usefulness. The present overview will include not only models for RA, but will briefly add models with related disease pathways such as psoriasis arthritis, Reiter's disease, ankylosing spondylitis, Lyme disease and septic arthritis (summarized in Table 29-2). However, there is a focus on the classic models for RA, currently commonly used in both industry and academia; the adjuvant arthritis models in the rat, the collagen induced-arthritis (CIA) and the collagen antibody-induced arthritis (CAIA).

## ARTHRITIS CAUSED BY INFECTIOUS AGENTS

Several infectious agents may invade joints where they persist and cause arthritis. Similar to most persistent infectious agents, a balance between the parasite and the host is usually achieved. Thus inflammatory consequences may not only be caused directly by the parasite but also by an aberrant inflammatory response of the host. When microorganisms are present in the target tissue, chronic autoimmunity could be maintained by different mechanisms such as superantigen-mediated T cell activation, a cross-reactive immune response, or the presence of adjuvant material enhancing autoantigen presentation. Several such arthritogenic agents have been described in experimental animals, and some of these mimic a corresponding infectious disease in humans.

### Mycoplasma Arthritides

Arthritis associated with mycoplasma infection is endemic among farm animals. It is also possible to induce arthritis in rodents after inoculation with *Mycoplasma arthritidis*. However, *Mycoplasma* bacteria are not easily found in joints with RA, although it may cause arthritis in individuals with severe B cell deficiency. Inoculation of mice induces a mild chronic arthritis in conjunction with the persistence of the microorganism, but this is driven by immune activation by a mycoplasma-derived superantigen.[2] In accordance with observations in humans, B cell-deleted mice are more susceptible to *Mycoplasma*-induced arthritis.

### Lyme Arthritis

*Borrelia* is a spirochete that may persist in joints and cause arthritis. The clinical picture is chronic, resembles RA, and is genetically associated with class II-DR4 MHC, as is RA. Live bacteria persist in the joints, but in many patients it has been difficult to identify the spirochete in the arthritic joints. Mice infected with *Borrelia* develop arthritis similar to the human version of the disease. Similar to humans, MHC controls susceptibility to arthritis, and the immune response associated with human class II MHC expressed in mice is directed to *Borrelia*-derived antigens.[3] The persistence of the spirochete seems to be a requirement for the development of the arthritis, although some mouse strains do not develop arthritis in spite of high levels of bacteria in the joints.

### Staphylococcal Arthritis

Septic arthritis is most commonly caused by a persistent infection of *Staphylococcus aureus*. The bacteria tend to be

**TABLE 29-2** Overview of Rodent Arthritis Models

| Model | Species | Genetics | Disease Characteristics | Reference |
|---|---|---|---|---|
| **Arthritis Caused by Infection** | | | | |
| Mycoplasma-induced arthritis | Rats and mice | More pronounced in B cell-deficient mice | Mild chronic arthritis | 2 |
| *Borrelia*-induced arthritis | Mice | Major histocompatibility complex (MHC) | Severe and erosive arthritis with spirochetes in the joints | 62 |
| *Staphylococcus*-induced arthritis | Rats and mice | MHC | Severe arthritis | 4 |
| *Yersinia*-induced arthritis | Rats and mice | LEW and SHR but not DA and BN rats | Severe arthritis with bacteria in the joints | 63 |
| **Arthritis Caused by Bacterial Fragments** | | | | |
| *Mycobacterium*-induced arthritis ("adjuvant arthritis" [AA]) | Rats | MHC, non-MHC genes (LEW >F344) | Acute and generalized inflammatory disease including erosive arthritis | 6 |
| Streptococcal cell wall-induced arthritis | Mice and rats | Non-MHC genes (LEW >F344), (DBA/1=Balb/c >B10) | Severe and erosive arthritis | 64 |
| **Arthritis Induced by Adjuvant** | | | | |
| Avridine-induced arthritis (AvIA) | rats | MHC (f) | Very severe, erosive, and chronic arthritis | 65 |
| Oil (mineral oil)-induced arthritis (OIA) | DA rats | non-MHC loci on chr 4, 10 | Acute and self-limited inflammation of peripheral joints | 10 |
| Pristane-induced arthritis (PIA) | Rats | MHC, non-MHC loci on chr 1, 4, 6,12, 14 | Chronic and erosive arthritis in peripheral joints<br>Can be passively transferred with ab T cells | 11 |
| PIA | Mice | MHC (q, d)?<br>Balb/c, DBA and C3H gene backgrounds | Chronic and generalized inflammatory disease also affecting joints | 17 |
| Mannan-induced psoriasis and psoriasis arthritis | Mice | B10.Q, B10.RIII.<br>Arthritis enhanced by mutation in Ncf1. | Both psoriasis and psoriasis arthritis developing a few days after injection mannan. Macrophage, gd T cell, and neutrophil dependent. | 20 |
| **Arthritis Induced By Cartilage Protein Immunization** | | | | |
| CII (heterologous or homologous CII in mineral oil)-induced arthritis (CIA) | Rats | MHC (a, l, f and u), non-MHC loci on chr 1, 4, 7, 10 | Chronic and erosive arthritis in peripheral joints | 66 |
| CII (heterologous or homologous CII in CFA) induced arthritis (CIA) | Mice | MHC (q and r), non-MHC loci on chr 1, 2, 3, 6, 7, 8, 10, 15 | Erosive arthritis in peripheral joints | 27,67 |
| CXI (rat CXI in IFA) induced arthritis | Rats | MHC (f, u) | Severe, chronic arthritis | 24 |
| Human proteoglycan (in complete Freund's adjuvant-induced arthritis) | BALB/c mice | MHC (d), several non-MHC loci | Chronic arthritis | 23 |
| Cartilage oligomeric matrix protein (COMP) (in mineral oil)-induced arthritis | Rats, mice | MHC (RT1u, H2q) | Severe but self-limited arthritis | 25,44 |
| G6PI induced arthritis | Mice | MHC (H2q), C3HQ>DBA/1>B10.Q | Severe but self-limited arthritis | 18,76 |
| **Antibody-Induced Arthritis Models** | | | | |
| Collagen antibody-induced arthritis (CAIA) | Mice | Balb/c>B10.RIII>B6 | Acute arthritis | 77 |
| KXBN serum-induced arthritis (SIA) | Mice | | Severe acute arthritis | 68 |
| **"Spontaneous" Arthritis Models** | | | | |
| HLA-B27 transgenic animals | Mice and rats | B27 heavy chain transgene | Ankylosing spondylitis, colitis, balanitis, arthritis | 5 |
| The MRL/lpr mouse (mutation in the *fas* gene controlling apoptosis) | Mice | lpr | Generalized inflammation as a part of lupus disease, which also affects joints | 53 |
| Stress-induced arthritis | DBA/1 mice | Non-MHC genes | Enthesopathic response with no evidence for immune involvement. A model for psoriasis arthritis. | 52 |

*Continued*

**TABLE 29-2** Overview of Animal Arthritis Models—cont'd

| Model | Species | Genetics | Disease Characteristics | Reference |
|---|---|---|---|---|
| Tumor necrosis factor (TNF) transgenic mice (overproduction of TNF) | Mice | TNF transgene | Erosive arthritis as well as generalized tissue inflammation | 54 |
| IL-1R antagonist-deficient mouse | Balb/c mice | IL-1Ra deficiency | Arthritis | 57 |
| Gp130 IL-6R mutant mouse | C57 Black mice | IL-6R mutation | Arthritis | 58 |
| KxBN | | TCR transgenic specific for a glucose-6-phosphate isomerase (G6PI)-derived peptide | Severe arthritis with autoreactivity to G6PI | 68 |
| *Zap70* mutation | Balb/c mice | Spontaneous mutation in *Zap70* | Severe arthritis with autoreactivity | 19 |
| Severe combined immunodeficiency (SCID) mouse | Mice | Local injection of fibroblasts into immunodeficient SCID mouse | Sustained destructive arthritis | 60 |

encapsulated in tissues including joint synovia and persist for years. Inoculation with certain *Staphylococcus aureus* strains induces septic arthritis in many mouse and rat strains.[4] Severe and prolonged arthritis develops in infected joints, mimicking human disease. Interestingly, protection of the host is critically dependent on the innate defense, such as neutrophils and complement, whereas the adapted immune response is not effective. Instead, the apparently aberrant adapted immune response promotes arthritis.

### Arthritis and Ankylosing Spondylitis Induced by Intra-cellular Bacteria

Some bacteria with the capacity to invade cells upon infection (e.g., *Yersinia*) are known to be related to postinfectious arthritides such as reactive arthritis and ankylosing spondylitis. These diseases are genetically associated with HLA-B27, a class I MHC allele of the B locus. It has been possible to reproduce the human disease to a large extent in HLA-B27 transgenic mice and rats.[5] In B27-transgenic rats, ankylosing spondylitis, balanitis, colitis, dermatitis, and arthritis occur spontaneously. However, if the rats are made germ-free, the joint manifestations are no longer present. This phenomenon indicates the importance of a so far unknown infectious agent. Importantly, the development of arthritis is most likely related to the triggering of inflammation by adjuvant fragments from the pathogen.

## ARTHRITIS CAUSED BY BACTERIAL FRAGMENTS

Postinfectious arthritis may develop after bacterial infections. The occurrence of arthritis can be dependent on several different bacteria-derived compounds, such as cell wall fragments, DNA, and heat shock proteins. Bacterial cell wall fragments are difficult to degrade and may cause prolonged activation of macrophages, also synovial macrophages. The first animal model for RA to be described was the so called *adjuvant arthritis* (AA) induced in rats after injection of mycobacterium cell walls suspended in mineral oil (i.e., complete Freund's adjuvant [CFA]).[6] Only rats (and not mice or primates) develop arthritis after mycobacterium challenge, although joint-related granuloma formation may occur also in humans treated with mycobacterium-containing vaccine. CFA is a potent adjuvant that activates a multitude of pattern recognition receptors, activating antigen-presenting cells and enhancing T cell immunity. Subcutaneous injection of CFA in rats leads to granulomatous inflammation in many organs, for example, the spleen, liver, bone marrow, skin, and eyes, and causes profound inflammation in peripheral joints. AA is severe but self-limited, and the inflammation subsides after 5 to 7 weeks. The mycobacterium cell wall fragments are most likely disseminated throughout the body and engulfed by tissue macrophages, which have difficulties in degrading the bacterial cell wall structures and are therefore transformed into an activated state, which trigger inflammation.

AA can be abrogated by elimination of the classic alpha/beta type of T cells, and spleen-derived T cells can transfer the disease. The specificity of such T cells has, however, not been reproducibly demonstrated, although some possibilities have been suggested, including bacterial structures and cross-reactive self-components. Although a role for heat shock proteins as T cell antigens has not been confirmed, they play a regulatory role for the development of arthritis. A minimal arthritogenic structure in the mycobacteria cell wall is the peptidoglycan component muramyl dipeptide. Interestingly, T cells do not recognize this structure, but it has potent adjuvant capacity because it activates the inflammasome by stimulating innate immune receptors (NOD2) and antigen-presenting cells. In addition, the unmethylated DNA of bacteria independently triggers arthritis in mice and contributes to arthritis severity of AA in rats. The bacterial DNA triggers Toll-like receptors on both antigen-presenting cells and inflammatory macrophages and will, therefore, interact with both T cell–dependent and inflammatory pathways. Another T cell–dependent arthritogenic pathway is triggered by the mineral oil in which the mycobacteria is suspended, as is discussed later in more detail. Thus, this classic "adjuvant-induced arthritis" is mediated by different and interacting pathways, dependent on both different mycobacterium cell components as peptidoglycans, DNA and heat shock proteins but also dependent on adjuvant activity mediated by the oil used to suspend the mycobacteria.

Postinfectious arthritis has also been observed to occur after streptococcal infections. A rapidly developing form of arthritis has been observed after systemic inoculation of

streptococcal cell wall fragments in rats and mice but not in primates.[7] Parenterally injected peptidoglycans rapidly disseminate throughout the body, including the joints. These structures are difficult to degrade for the macrophages and, as a consequence, synovial macrophages are persistently activated. T cells are necessary for the initiation and perpetuation of the arthritis.

Chronic parodontitis caused by *P. gingivalis* has been suggested to be involved in the initiation of RA,[8] but so far no arthritis has been induced in animal models by using live bacteria or by immunization with *P. gingivalis*-derived components.

## ADJUVANT-INDUCED ARTHRITIS

The induction of arthritis in rats was found to be not only dependent on the mycobacteria but also the oil into which the mycobacterium fragments were suspended (reviewed in[9]). Interestingly, some oils were found to support the induction of arthritis whereas others did not. Many years later it was noted that the mineral oils that supported the induction of arthritis were in fact arthritogenic by themselves.[10] It was also found that subcutaneous administration of nonbacterial adjuvant compounds, such as pristane, hexadecane, and squalene, were highly effective in inducing arthritis.[11] These adjuvant compounds in most cases produce inflammation confined to the joints and offer more appropriate experimental models for RA than the earlier commonly used AA (i.e., mycobacterium in oil-induced arthritis) model.

Mineral oil-induced arthritis (OIA), avridine-induced arthritis (AvIA), pristane-induced arthritis (PIA), hexadecane-induced arthritis, and squalene-induced arthritis in the rat share many common features but differ by the degree of chronic development (Figure 29-1). They are induced with adjuvant compounds that lack immunogenic capacity (i.e., no specific immune responses are elicited). Instead they are rapidly spread throughout the body after a single subcutaneous injection, penetrate through cell membranes into cells, and interact with as yet unknown cell surface receptors and intra-cellular proteins. One or two weeks after injection, arthritis suddenly develops. The arthritis appears in the peripheral joints, with a similar distribution as seen in RA. Occasionally other joints are involved, but systemic manifestations in other tissues have so far not been reported. In certain rat strains, especially in the PIA model, the arthritis proceeds as a chronic relapsing disease. Interestingly, a systemic immune response occurs that leads to production of antibodies to RA33 and rheumatoid factors but not ACPA, whereas an immune response to cartilage proteins appears in the more chronic development of the disease.[12] A role for cartilage proteins in regulation of disease activity is seen because the disease can be prevented and, in fact, therapeutically ameliorated by nasal vaccination with various cartilage proteins. Interestingly, the first acute phase of the disease is class II MHC–dependent and αβ T cells play a critical role in all stages of the disease. T cell transfer of the disease seem to be oligoclonal rather than monoclonal, and so far antigen-specific T cells have not been identified.[13] A role for environmental infectious agents is not likely because no difference in disease susceptibility could be seen in germ-free rats, although only conventional rats respond to heat shock proteins.[14] There is so far no evidence for recognition by lymphocyte receptors or receptors involved in the innate immune system. Surprisingly, some of the arthritogenic adjuvants are in fact components already present in the body before injection. For example, pristane is a component of chlorophyll and is normally ingested by all mammals including laboratory rats. Pristane is taken up through the intestine and spread throughout the body. However, they all share the capacity to penetrate into cells where they could change membrane

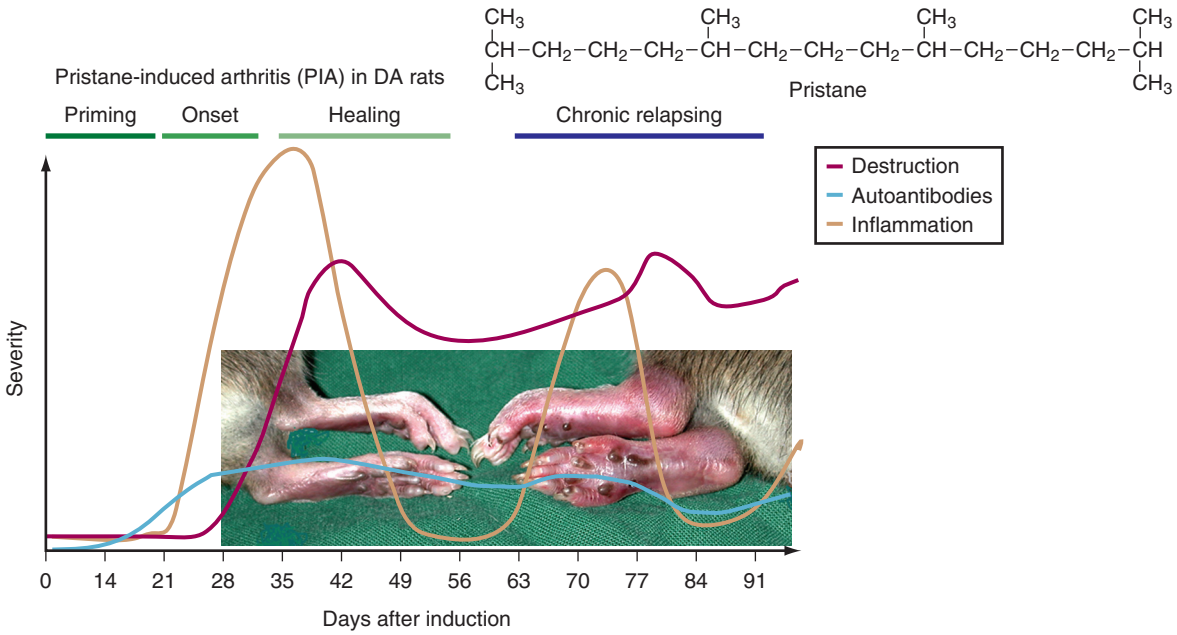

**Figure 29-1** Pristane-induced arthritis in dark agouti rats; induced with pristane subcutaneously. Development of severe and chronic relapsing arthritis starting 10 to 14 days after injection

fluidity and modulate transcriptional regulation and in higher doses induce apoptosis. The injection route and dose is critical (i.e., it is decisive for which cell is first activated and to what extent).

The PIA model has been subjected to genetic analysis showing that the disease is polygenic,[15] and the identified loci control distinct phases of the disease such as arthritis onset, clinical severity, joint erosion, and chronicity. Some of the underlying genes have been identified. The strongest effect is mediated through a polymorphism of the *Ncf1* gene of both inbred and wild rat populations.[16] The *Ncf1* gene codes for the p47phox component of the NOX2 complex and controls the oxidative burst. Surprisingly, a higher oxidative burst capacity was associated with more severe arthritis. The effect was found to operate before T cell activation, and therefore it also controls the degree of autoimmunity, linking innate and adaptive immunity. Importantly, the class II MHC region, controlling the adaptive T cell response, and a C-type lectin gene cluster *(APLEC)*, which are likely to have importance in uptake of antigen to antigen-presenting cells also control PIA.

AA is not easily inducible in species other than rats. Of the above mentioned AIA models, only PIA has been described in mice.[17] However, the induction of PIA in mice requires repeated intraperitoneal injections of pristane, which triggers a widespread inflammatory disease with a late and insidious onset. The induced disease mimics systemic lupus erythematosus (SLE) rather than RA.[18] The disease is clearly different from PIA in the rat; the same inducing protocol does not induce disease in the rat, and the disease course and characteristics are different. Another adjuvant-related model is the induction of mild arthritis after intra-articular injection of agents that activate macrophages, such as unmethylated DNA. It has recently been found that several mouse models previously believed to be spontaneous are critically dependent on adjuvants and should therefore be classified as AIA. From the observation that a BALB/c mouse substrain in Japan spontaneously developed arthritis a causative amino acid replacing mutation in the *ZAP70* gene was identified.[19] The mutation *(W163C)* caused a weaker TCR mediated signalling and the development of arthritis was preceded by increased levels of IL-17 producing autoreactive T cells. The *Zap70* mutation led to defective positive selection and the emergence of autoreactive T cells that attached the joints. As a result, both rheumatoid factors and CII reactive antibodies were detected in the mice. The arthritis, however, did not develop in specific pathogen-free conditions and it could be shown that injection of beta-glycan or mannan induced the arthritis. Thus this model seems to be an AIA in the mouse. The resulting arthritis may however differ depending on the inducing agent and the genetic background. For example, injection of mannan in certain mouse strains with a deficiency in reactive oxygen species production results in a disease mimicking psoriasis arthritis rather than the classic RA.[20]

Also some other spontaneous arthritis models, the KxB/N model or the IL-1R deficient mouse, are mediated by a likely adjuvant component because arthritis was strongly attenuated under germ-free conditions.[21,22] The causative arthritogenic effect was mediated by intestinal bacterias, segmented filamentous bacteria (SFB),[21] and lactobacillus,[22] respectively.

Taken together, there is today a set of useful adjuvant type of arthritis models in both mice and rats.

## CARTILAGE PROTEIN-INDUCED ARTHRITIS

Arthritis is inducible with several different cartilage-proteins, such as aggrecan,[23] type XI collagen CXI,[24] cartilage oligomeric matrix protein (COMP),[25] and CII.[26] These various models have different characteristics and genetics. CIA, induced with CII, is today the most commonly used model for RA; it was first demonstrated in the rat[26] and was later reported using other species, such as mice[27] and primates.[28] Today it is the most commonly used model for RA.

### Collagen (II)-Induced Arthritis

Immunization with the major collagen in cartilage, type II collagen (CII), leads to an autoimmune response and, as a consequence, a sudden onset of severe arthritis. It is usually necessary to emulsify the CII in adjuvant, such as mineral oil in the rat and complete Freund's adjuvant in the mouse, but the disease can be distinguished from the various forms of AA. The susceptibility of the CIA model varies considerably depending on the experimental animal strain, the adjuvant used, and on whether CII used is of self or nonself origin.

In both rats and mice immunized with heterologous CII, a severe, erosive polyarthritis develops 2 to 3 weeks after immunization but usually subsides within 3 to 4 weeks (Figure 29-2). The most commonly used DBA/1 strain thus develops a severe but only an acute disease. However, a genetic influence is obvious because mice on C57Bl backgrounds develop a milder arthritis, which later may develop into a more chronic relapsing disease course (Figure 29-3). In all of the models, the erosive inflammatory phase is followed by a healing phase, with pronounced formation of new cartilage and bone that clinically can be difficult to distinguish from active inflammation. The disease is critically dependent on both a T and a B cell response to CII, and pathogenic antibodies play a role in the inflammatory attack on the joints.[29] The CAIA is inducible with certain CII-specific monoclonal antibodies[30] (Figure 29-4). These CII-specific antibodies bind to the cartilage and destabilize the cartilage matrix. Subsequently, the inflammatory response is triggered with infiltration of antibodies into cartilage matrix, fixation of complement attraction of neutrophilic granulocytes, and activation of FcR expressing inflammatory cells in a process independent of the immune system.[31] Interestingly, the epitopes recognized on CII contain arginines that potentially can be citrullinated. The major CII epitopes are citrullinated and monoclonal antibodies specific for the citrullinated peptide induce arthritis, showing an important link to RA.[32]

Mice and rats are less susceptible to immunization with homologous CII as compared with heterologous CII, but once started it could be more severe and is often more chronic. The pathogenic events in the chronic disease phase are largely unknown but are most likely dependent on both autoreactive B and T cell activity. Nevertheless, the CIA model is the most extensively investigated model for RA and has given valuable insights into the genetic control of the arthritic process and of the autoimmune

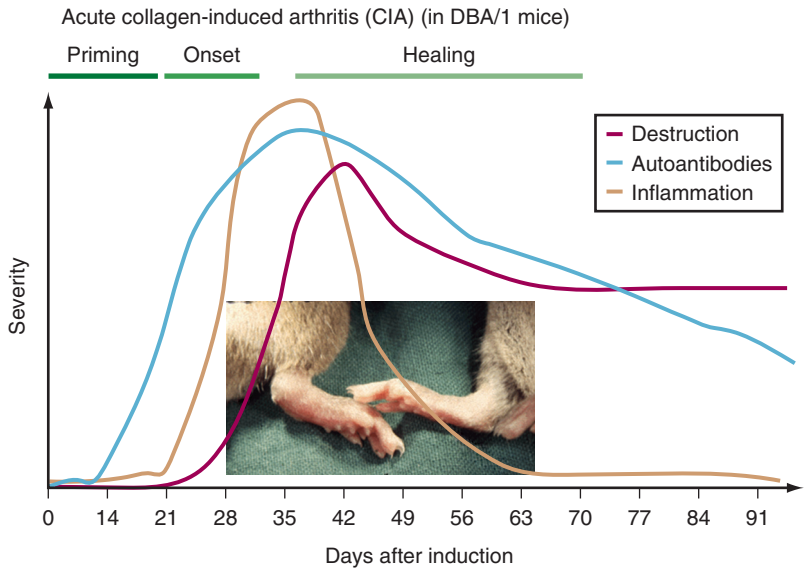

**Figure 29-2** Collagen-induced arthritis in DBA/1 mice. Induced after immunization with heterologous (bovine, chicken, rat) type II collagen emulsified in complete Freund's adjuvant. Severe arthritis starts 3 to 4 weeks after immunization. Although the arthritis is severe and causes dramatic erosions and bone remodeling, there is no chronic relapsing inflammatory disease course.

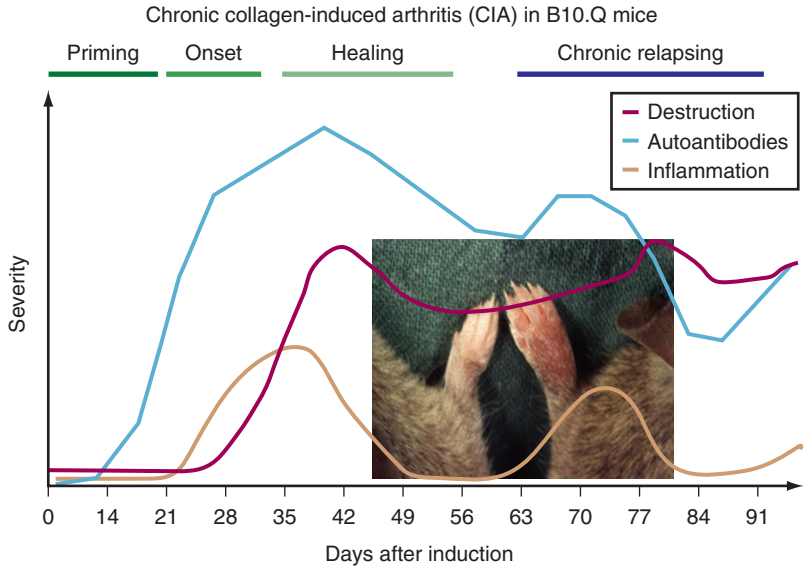

**Figure 29-3** Collagen-induced arthritis in B10.Q mice; induced after immunization with rat type II collagen emulsified in complete Freund's adjuvant. Mild arthritis starts 3 to 5 weeks after immunization. The arthritis is mild but causes inflammatory joint erosions and bone remodeling. It is, however, often followed by a chronic disease with inflammatory relapses.

interactions with cartilage. It has also been useful for the development of new therapeutic approaches and for drug screening.

## Genetic Basis of Collagen-Induced Arthritis

Susceptibility to CIA varies dramatically between different inbred strains. The CIA is a complex, polygenic disease, in similarity with the AA models described in the preceding text. In the CIA model, the autoimmune process is already determined by the induction through immunization with a defined antigen. Not surprisingly, the class II MHC polymorphism is important for determining susceptibility, but there is also a major influence by a large number of genes outside the MHC region. The major gene regions have been identified through genetic segregation experiments in both mice and rats, which have given an overall picture of the genetic inheritance of the susceptibility.[33] As in other complex diseases, these genes operate in concert and can only by identified through isolation in a controlled genetic and environmental context. Class II MHC genes *(Aq)*, *Ncf1*, and complement C5 have until now been positioned from genetic analysis. The *Ncf1* gene was defined through analysis of PIA and CIA in rats.[34] A spontaneous mutation in the mouse *Ncf1* gene, when combined with the CIA-susceptible class II MHC allele Aq in the C57Bl/10 mouse, causes a chronic relapsing form of CIA.[35] In addition, these mice tend to develop a severe form of chronic arthritis in

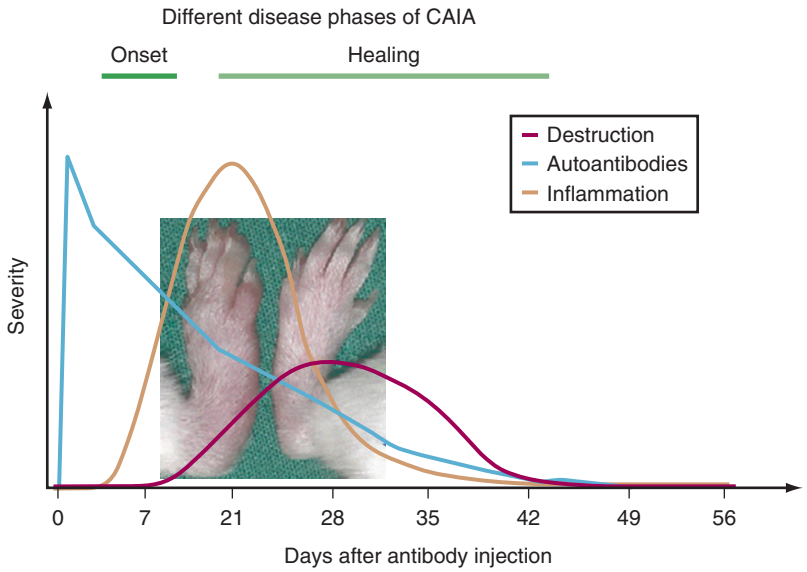

**Figure 29-4** Collagen antibody -induced arthritis in Balb/c mice; induced after intravenous injection of a defined set of monoclonal antibodies to type II collagen. Mild arthritis starts 48 hours after injection, and severe arthritis starts after an additional boost with injection of LPS intraperitoneally. The arthritis is acute with mild joint erosions but with no bone remodeling. The disease is acute and resolves within a few weeks.

the postpartum period, with the spontaneous development of autoimmunity to CII. Another genetic polymorphism of importance is the complement C5, which is deficient in many mouse strains. The deficiency leads to a relative resistance to CIA, suggesting a role for complement pathways in arthritis, which in fact is the opposite of its role in mycoplasma-induced arthritis. A role for alternative complement pathways as well as Fc receptor-mediated pathways have been demonstrated by using both CIA and the CAIA models.[36,37] The rapid progress of genome-wide association analysis of large human cohorts today gives direct information on involved genes and gene clusters in common disease such as RA. However, animal models are needed to understand their functional relevance, and for this the genes that control the corresponding disease in the animals need to be identified.

## Autoimmunity Associated with the Major Histocompatibility Complex in Collagen-Induced Arthritis

Early observations with use of the CIA model in both mice and rats indicated a role for the MHC region. In the mouse, CIA induced with either heterologous or homologous CII is most strongly associated with the $H2^q$ and $H2^r$ haplotypes, whereas most other haplotypes, such as b, s, d, and p, are relatively resistant.[38] The major underlying gene within the $H2^q$ haplotype has been identified as the $A^q$ beta gene.[39] Moreover, the immunodominant peptide derived from the CII molecule bound to the arthritis-associated q variant of the A ($A^q$) molecule has been found to be located between positions 259 and 271 of CII.[40] This peptide can be glycosylated on the central lysine side chain and is recognized by most of the CII-reactive T cells. Interestingly, the peptide is also bound by DR4 (DRB1*0401/DRA) and DR1 molecules (i.e., the shared epitope, which is associated with RA). Mice that transgenically express DR4 or DR1 are susceptible to CIA and respond to CII259-271 peptide and CII-reactive T cells from RA patients.[41] These findings suggest a model for studies of RA that not only mimic some basic pathogenic events but might also share some critical structural similarities.

Arthritis is also inducible in mice strains that do not express q or r. A commonly used model is to induce arthritis with high doses of chicken or bovine CII emulsified in mycobacterium tuberculosum-containing CFA. T cell autoreactivity to CII, however, is not reproducibly demonstrated and there is no verified T cell response to CII. It is likely that the T cell reactivity is directed to a contaminant in the preparation such as another matrix protein or the pepsin used for the preparation. Such T cell reactivity could help B cells produce antibodies to CII, which would explain the development of arthritis.[42]

It is important to emphasize that the structural interaction between class II $MHC^+$ peptide complexes and T cells does not give us the answer to the pathogenesis of CIA (or RA), but rather, a better tool for further analysis. An important question is how the immune system interacts with the peripheral joints (i.e., how autoreactive T and B cells are normally tolerized and what happens in the pathologic situation after their activation by CII immunization). Most of the T cells reactive with the rat CII259-271 peptide do not cross-react with the corresponding peptide from mouse CII. The difference between the heterologous and the homologous peptide is position 266, in which the rat has a glutamic acid (E) and the mouse an aspartic acid (D), which leads to a weaker binding of the mouse peptide to $A^q$. The importance of this minor difference was demonstrated in transgenic mice expressing CII mutated to express a glutamic acid at this position.[43] When mutated CII was expressed in cartilage, the T cell response to CII was partially but not completely tolerized. The mice were susceptible to arthritis, but the incidence was low, similar to what is seen in mice immunized with homologous CII. This finding shows that a normal interaction between cartilage and T cells leads to the activation of T cells, but with less capacity to induce

arthritis or with regulatory properties. These CII autoreactive T cells may under extreme circumstances (such as CII immunization) be pathogenic. In contrast, B cells reactive with CII are not tolerized, and as soon as the T cells are activated, even in a partially tolerized state, they may help B cells to produce autoreactive and pathogenic antibodies. It is possible that a similar situation may exist in humans that could explain the difficulties in isolating CII reactive T cells, compared with the relative ease in which CII-reactive B cells can be detected in the joints.

## Induction of Arthritis with Other Cartilage and Joint-Related Proteins

### Type XI Collagen-Induced Arthritis

The type XI collagen (CXI) is structurally similar to CII and is to a large extent co-localized. CXI is a heterotrimer with three different α chains where one is shared with CII (the a3 chain). Both heterologous and homologous CXI induce arthritis in rat strains.[24] Interestingly, the induction with homologous CXI gives a chronic relapsing disease, which is distinctly different from the heterologous CXI-induced disease and CII-induced CIA.

### Cartilage Oligomeric Matrix Protein-Induced Arthritis

Another cartilage protein is cartilage oligomeric matrix protein (COMP). Homologous COMP induces arthritis in both rats and mice.[25,44]

### Proteoglycan (Aggrecan)-Induced Arthritis

Other major components of joint cartilage are proteoglycans, of which the largest is aggrecan. Immunization of Balb/c mice with foetal human aggrecan induces chronic arthritis.[23] Both B and T cells are involved in the pathogenesis. Autoreactive T cells have been isolated and respond to the G1-domain of aggrecan in which neoepitopes are created.[45] T cell receptor transgenic mice spontaneously develop arthritis at old age. The disease has been genetically mapped and share many gene regions in common with CIA.

### Antigen-Induced Arthritis

Antigen-induced arthritis is a classic model of RA that is induced by immunizing animals with a foreign antigen, usually bovine serum albumin, and subsequently injecting the same antigen into a joint. A pronounced T cell-dependent immune complex-mediated and destructive arthritis develops in the injected joint as a result. The model is very well controlled and has been used to understand the effector phase of joint inflammation and cartilage destruction.[46]

### Glucose-6-Phosphate Isomerase-Induced Arthritis

The successful induction of arthritis after immunization with recombinant glucose 6 phosphoisomerase in adjuvant[47] stems from the identification of the K/BxN model in which transgenic T cells specific for glucose-6-phosphate isomerase (GPI) leads to spontaneous arthritis in NOD mice.[47a] The GPI-induced arthritis is MHC dependent and associated with the H2q haplotype (as CIA), and GPI peptides with an Aq-binding capacity can induce arthritis.[48] GPI has a unique affinity for cartilage, because it binds with high affinity to cartilage proteoglycans[49]; spontaneous immune activation in the K/BxN mouse seems to primarily arise in lymph nodes draining joints.[50] Thus, although GPI is ubiquitously expressed, the immune system may recognize its presence in the joints. The GPI-induced arthritis is T and B cell dependent. Interestingly, depletion of FoxP3-positive Tregs leads to a chronic disease course.[51]

# SPONTANEOUS ARTHRITIS

Many of the classic inbred mouse and rat strains tend to spontaneously develop arthritis, in particular under certain environmental influences (Table 29-3). In some strains, such as DBA/1, the grouping of males easily induces intermale aggressiveness; such stress seems to be associated with development of severe arthritis.[52] This stress-induced arthritis is very different from inflammatory arthritis models such as CIA and have less inflammatory synovial infiltrate, but with enthesopathy and new cartilage and bone formation, more similar to psoriasis arthritis than RA. There are also a number of genetic mutations that strongly enhance arthritis development. One such mutation occurs in the *Fas* gene, of critical importance for apoptosis. In the MRL mouse background, arthritis develops with a severe lupus disease.[53] Other examples are the previously mentioned mutations in the *Ncf1*[35] or *ZAP70*[19] genes.

## Spontaneous Arthritis in Genetically Modified Strains

Importantly, models that develop spontaneous arthritis have been possible to create by genetically modifying mouse strains. The prime example of this is the demonstration that overexpression of tumor necrosis factor (TNF) leads to severe arthritis.[54] This model has been extremely useful in delineating the role of TNF in mediating arthritis. Other genetic mutations leading to overexpression of TNF, such as deletion of an upstream regulatory element that controls TNF secretion in fibroblast[55] or the deletion of DNasII,[56] which leads to aberrant secretion of TNF by chronically stimulated macrophages, also lead to spontaneous development of severe arthritis. Mice overproducing TNF develop

**TABLE 29-3** Some Environmental Effects on Arthritis Models

| Environmental Effect | Effect on Arthritis | Reference |
|---|---|---|

| Darkness | + | 74 |
| Infections | –/+ | 14,21,75 |

+, Increased arthritis; –, decreased arthritis.

arthritis through activation of the innate immune system and not dependent of adaptive T and B cell immunity. Another important lesson from the TNF overproducing mice was that it primarily led to the development of arthritis, although in some situations colitis and encephalomyelitis also develop.

Subsequently, several other genetically modified mouse strains developing arthritis have been reported. A mouse deficient for the IL-1 receptor antagonist[57] developed arthritis that not only affected the downstream effector functions but could also be dependent on T cell activation.

A mutation in the gp130 IL-6 receptor was observed to lead to arthritis in elderly mice.[58] Interestingly, the mutation led to an accumulation of polyclonal autoreactive $CD4^+$ T cells that secreted inflammatory cytokines, indicating a regulatory role of the IL-6 receptor of the adaptive immune system.

Another type of spontaneous arthritis was observed in a T cell receptor transgenic mouse in which the TCR recognizes a peptide derived from the ubiquitously occurring protein glucose-6-phosphoisomerase (G6PI) bound to the class II MHC protein Ag7, the KxBN mouse.[59] However, as discussed in a preceding section, the arthritis requires SFB bacteria in the intestinal flora, indicating that this disease is not strictly spontaneous but rather is induced by a bacterial adjuvant stimulation. The pathogenic effector pathway in this model is dependent on antibodies reactive with G6PI. This serum-induced arthritis (SIA) can be transferred with sera from K/BxN mice and the antibodies bind to precipitated GPI on the cartilage surface, mimicking the pathogenesis of anti-CII antibodies in the CAIA model. The use of the G6PI antibody-induced arthritis has been instrumental in finding early inflammatory steps in the joint attack, which involves complement activation through the alternative pathway, and neutrophil infiltration. Clearly, the joints are specifically targeted in the disease and it remains to be determined how T cells and antibodies recognize this systemically expressed autoantigen in a joint-specific context.

Another type of model is induction arthritis after transplantation of human synovial fibroblasts into immune-deficient SCID mice.[60,61] The same type of arthritis develops after transfer of murine fibroblast cell lines. This model is likely to reflect inherent properties of fibroblast-mediated mechanisms showing different features compared with other arthritis models like CIA and PIA.

These models most likely represent various aspects of the processes leading to arthritis, which will be determined by the transgene or defective gene, or due to transplantation of specific cells.

## USE OF ANIMAL MODELS

### Increasing the Knowledge of Disease Pathways

An ideal model for human RA should mimic the complexity of the human disease in being polygenic and dependent on environmental factors. The animal models have the advantage that both genetics and environment can be better controlled. There are many forms of arthritis, and the different clinical varieties are likely to continue to be subdivided just as has happened with ACPA+ RA and seronegative RA, whereas animal models represent very divergent pathways and diseases that lead to arthritis.

Ideally, animal models should mimic the various subtypes of RA. With increasing knowledge of RA, such as the identification of ACPA as a predictive biomarker, and the identification of new genes associated with RA, there will also be new demands on the animal models. Thus, an animal model does not yet exist that reflects the production of ACPA nor has a properly humanized mouse strain been developed that pathophysiologically mimics the genetic polymorphism identified in humans. To introduce new genes (e.g., human class II MHC) or environmental factors (e.g., smoking), a proper and well-controlled genetic and environmental context is critical. For example, the introduction of the human class II MHC as transgenes in the mouse has led to a number of artifacts, some of them related to the non-physiologic interactions between human and mouse genes. However, as long as the mouse models have been studied with a well-controlled genetic and environmental context, they have and will contribute detailed information on the molecular pathogenesis that leads to arthritis. For this work, the possibility to genetically modify both mice and rats is a powerful tool, and the possibility to make controlled experiments is a critical advantage.

### Developing New Therapeutic Strategies

To test new drugs and therapies, it will be necessary to select from the different models available. Obviously there is no optimal model for RA, and there will never be one. The models described, however, are useful because they represent different aspects of RA pathogenesis. Thus, depending on the questions to be asked or symptoms to be treated, different models may be used. The most common model used today to test new therapeutic approaches is the CIA model, which should be included as a reference model. The usefulness of this model has been confirmed with the anti-TNF treatment, which was subsequently introduced in RA.

Recapitulating the three stages through which RA develops—priming, onset, and chronicity—reasonable criteria are that the animal models should be useful for studies of specific pathways of importance in these stages. A common mistake is to only use acute models and to only use disease prevention and not established chronic disease as a read out. It is also of critical importance to be aware of the specific environmental influences on arthritis development in rodents. Of particular importance are stress effects which are easily produced by mixing mice from different litters in the same cage and which will lead to cage-dependent effects. Other important factors are sex hormones and, most likely, neurohormones, which play an important role in modulating disease activity—seen as effects by oestrus cycling, pregnancy, and light effects. Clearly, not only environmental effects need to be controlled, but also genetic effects. The control of genetics is usually achieved by testing standardized inbred strains. The problem is that these vary considerably between different colonies, mainly because of genetic contamination. In spite of these problems, there is no question that both environment and genetics can be better controlled in experimental animal models than in studies directly involving the human population.

## ETHICAL CONSIDERATIONS

One important drawback of using experimental models for RA is suffering of animals. However, in the light of various human activities that use animals, the use of them in research seems to be the easiest to defend. In fact, it would be unethical not to use them for research because it would prohibit further understanding of human diseases, thereby letting humans suffer from diseases that will be possible to cure or prevent. It should also be emphasized that the recent development of animal models for RA has refined them to be of more specific use, which has decreased animal suffering. For example, the historically most commonly used model for RA, the mycobacterium-induced AA, is a systemic and severe inflammatory disease, whereas pristane-induced arthritis and collagen-induced arthritis are more specific disease of the joints.

## CONCLUSION

Experimental animal models are essential tools not only for investigating the basic mechanisms leading to RA but also for the development of new therapies. Many models have been described, and each represents different aspects of the disease; it is therefore important to use different models. It has been emphasized that the models used should reflect essential clinical hallmarks of RA, and they should reflect the fact that RA is a polygenic disease triggered by unknown and multifactorial environmental factors.

CHAPTER 30

# Neuronal Regulation of Pain and Inflammation

Camilla I. Svensson • Linda S. Sorkin

**KEY POINTS**

- Pain signaling is amplified by inflammation.
- Peripheral sensory neurons have efferent functions that contribute to inflammation, including axon and dorsal root reflexes.
- Neurogenic inflammation results in flare, edema, and increased pain.
- The sympathetic nervous system modulates (enhances or attenuates) many immune cell types via adrenergic receptors.
- Vagal nerve stimulation attenuates disease activity in models of inflammatory arthritis.
- Neural control of inflammation involves multiple feedback loops involving somatic, sympathetic, and parasympathetic nervous systems and the hypothalamic-pituitary-adrenal axis.

Pain historically was viewed as a symptom and not a contributing factor to the inflammatory process. Nonetheless, in the early 1900s, papers began indicating that stimulation of dorsal roots and dorsal root ganglia (DRG) neurons results in peripheral vasodilation,[1] suggesting that sensory neurons not only conduct information to the spinal cord but also have an efferent function. Thus the foundation was laid for future investigators to show that the four cardinal signs of inflammation—erythema and warmth (secondary to vasodilation), swelling (secondary to plasma extravasation), and hypersensitivity (pain secondary to alterations in the excitability of nearby sensory neurons)—can result from neural activation and that thermal, mechanical, and chemical damage to skin is sufficient to trigger these reflexes.

These "so-called" axonal and dorsal root reflexes lead to release of bioactive substances from the peripheral nerve endings, which in turn act on target cells in the periphery, such as mast cells, leukocytes and lymphocytes, and vascular smooth muscle cells. This phenomenon is referred to as "neurogenic inflammation." Thus a bidirectional relationship exists between the inflammatory process and sensory activation. The nervous system is activated by inflammatory mediators, which leads to increased excitability of peripheral nociceptive sensory fibers, causing inflammatory pain. Conversely, the nervous system feeds back on the peripheral inflammatory process. This effect is achieved by output systems at different levels, including primary afferent fibers (axonal reflex), spinal cord (dorsal root reflexes), and the brain (neuroendocrine functions). Our view of the interaction between the inflammatory process and the nervous system has expanded to include both the sympathetic and parasympathetic efferent nervous systems.

A 1903 report concluded that the sympathetic nerve influenced the course of inflammation by nervous functions other than vasoconstriction and vasodilatation.[2] Since then, several interactions between the sympathetic nervous system and the immune system have been identified. Lymphoid tissue is highly innervated by sympathetic nerve fibers, and in primary and secondary lymphoid tissues, sympathetic nerve terminals are found in close proximity to immune cells.[3] Whereas multiple neuromediators are released from sympathetic terminals, the majority of research has focused on the role of norepinephrine. Both pharmacologic and molecular biologic investigations have shown that most immune cells express functional adrenergic receptors, which translate neuronal signals into immune cell signals. The immune system can be influenced (enhanced or attenuated) by various adrenergic receptor agonists or antagonists.[4] A role for the parasympathetic nervous system, in particular the vagus nerve, in immune regulation has also been demonstrated,[5] although the efferent linkage is a matter of heated debate.[4]

The importance of intact communication between brain and inflamed tissue has long been clinically recognized. In the early 1960s, it was known that disturbing this linkage—for example, by a stroke—resulted in reduced inflammation on the paralyzed side in patients with rheumatoid arthritis (RA).[6] It soon became accepted that an intact innervation was permissive for peripheral inflammation. However, protection of the affected limb from inflammatory disease was present after paralysis as a result of stroke and loss of upper motor neurons, as well as after loss of lower motor neurons and peripheral innervation.[6-9] Because these two mechanisms are very different, it is difficult to ascertain the common means of protection.

Observations in which normally symmetric inflammation was confined to the innervated/normal limb and was absent or greatly reduced in the mirror-image, paralyzed limb have been confirmed in animal experiments, substantiating this viewpoint.[10] However, some investigators have suggested that the protective effect was due to immobilization rather than denervation. In the past few years, the intriguing possibility that the protective effect of denervation is not strictly neural but rather is the result of a somatotopic-specific inhibition of vascular leakage induced by inflammation has started to penetrate the literature.[11] In summary, major advances have been made in deciphering the details of how the nervous system modulates the immune

system, and although it is clear that important two-way interactions occur between these systems, it is important to note that many mechanisms of that communication need to be unraveled.

## PRIMARY AFFERENT FIBERS

Nociceptors—that is, peripheral receptors that signal pain—are classically thought to transmit information regarding real or impending tissue damage from external sources. Evidence is accumulating that, in addition to sensing changes in the interface between self and the outside environment, many nociceptive fibers signal variations in acidity, temperature, carbon dioxide, and the metabolic state of the internal environment from a predetermined set point. Thus nociceptors can also be thought of as homeostatic sensors and are elements of a feedback loop.[12,13] During chronic inflammation and pathologic pain states, these feedback mechanisms frequently go awry and become players in the pathology.

Nociceptors are called "free nerve endings" because they are not encapsulated or associated with traditional receptor structures, although they are frequently in close contact with small distal blood vessels, lymphatic vessels, and mast cells.[14] This anatomic proximity suggests a functional relationship (see later section "Sensitization"). Cutaneous nociceptors are associated with Aδ (finely myelinated) and C (unmyelinated) axons. A different nomenclature is employed for afferent fibers from joint and muscle, which are known as group I-IV fibers. Group III and IV fibers are very similar to Aδ and C fibers, respectively, in that group III fibers are finely myelinated and group IV fibers are unmyelinated, and both classes have a large proportion of nociceptors. All primary afferent fibers are glutamatergic, and many contain one or more neurotransmitters, notably peptides, including substance P (SP), calcitonin gene–related peptide (CGRP), somatostatin, and galanin. Chemically sensitive afferents are activated and/or sensitized by a wide variety of tissue injury products, including inflammatory mediators such as pro-inflammatory cytokines, eicosanoids,[15-17] glutamate,[18,19] and protons (acidity).[17]

### Skin

Many Aδ and C fibers are polymodal nociceptors—that is, they respond to tissue-damaging levels of mechanical, thermal, and/or chemical stimulation.[20,21] Others are specific sensors for mechanical mechanisms, heat, or cold.

### Joint Afferents

Although most joint structures are innervated, importantly, they do not have equivalent innervation density or signal pain. Nociceptors are not found in cartilage and innervate only the outer third of the menisci; however, nociceptors do innervate synovium, fibrous capsules, ligaments, and bone. Only 20% of fibers in articular nerves are myelinated, with the preponderance being nociceptive finely myelinated group III fibers. Unmyelinated fibers are equally distributed between sympathetic efferent and group IV sensory fibers, with nociceptors comprising almost half of the total population.[22] Many group IV nociceptive fibers are normally quiescent and do not respond to normal range of movement. Some fire action potentials (APs) only after tissue damage and therefore are referred to as silent nociceptors (see later discussion). During inflammation, these fibers may become sensitized (see later discussion) by mediators such as prostaglandin $E_2$, whereupon even movements in the normal range can elicit APs. Other group IV nociceptors are activated predominantly or selectively by noxious levels of pressure or joint hyperrotation.[23] Sympathetic fibers regulate the blood flow in the joint and, via direct or indirect mechanisms, regulate articular vessel permeability.[24]

### Fascia

Fascia are innervated by group III and IV fibers[25-27] concentrated in the outer layers next to the skin, with only sparse innervation of the inner layer overlying the muscle. Collagen fiber bundles do not appear to be innervated by nociceptors.[27] Group III fibers are exclusively mechanoreceptors, whereas the group IV fibers include a large percentage of polymodal nociceptors that respond to heat/cold and chemical factors, as well as to pinch and pressure.

### Muscle

Among the nociceptive afferents that respond to high intensities of local pressure, almost all are also chemoreceptive.[28] Intraneural microstimulation of single group III and IV muscle afferent fibers in human volunteers produces sensations of well-localized muscle cramping that is clearly distinguishable from the sharp pain produced by stimulation of tendon afferents.[29,30]

### Mechanically Sensitive Afferents—"Silent Nociceptors"

Nociceptors of the skin and joints include a class called *mechanically insensitive afferents* or silent nociceptors.[31,32] These nociceptors are normally unresponsive, but once they are sensitized by inflammation or tissue damage, they have greatly reduced thresholds. Their chemical activators are released from injured tissue, from the vasculature via plasma extravasation, from activated resident cells such as mast cells and keratinocytes,[33] and/or from infiltrating immune cells. After sensitization they respond to both normally innocuous and noxious stimulation, frequently including light touch and normal joint movement.

### Sensitization

Sensitization is defined as increased responsiveness and reduced threshold to stimulation, and it occurs at all levels of the neuraxis. It can occur instantaneously or have longer latency and duration. Short-term sensitization can result from receptor phosphorylation or dephosphorylation or trafficking of receptors and channels into or out of the plasma membrane. Longer-lasting sensitization can occur after increased mRNA translation and synthesis of receptors and ion channels.[34]

In the primary afferent, protein synthesis may occur in DRG and protein transport to the terminal may be required[35]; alternatively synthesis may occur in the terminal

itself, obviating the necessity for transport time.[36] Sensitization may include activation of satellite cells in DRG and of astrocytes and microglia in the central nervous system (CNS), with a resultant release of cytokines and other proinflammatory mediators. Release of cytokines within the CNS contributes to pathologic pain and illness behavior.[37] After chronic injury, macrophages and other immune cells may also infiltrate into the DRG and CNS.[38,39]

## EFFERENT FUNCTIONS OF PRIMARY AFFERENT FIBERS

### Neurogenic Inflammation

In the absence of actual tissue injury, activation of peripheral nerves or their terminals results in peripheral release of the same neurotransmitters as are released from their central (spinal) terminals. Action potentials in nociceptors going toward the spinal cord (orthodromic) result in pain sensations. However, action potentials traveling away from the spinal cord (antidromic) lead to a peripheral release of neurotransmitters throughout all branches of that fiber, a process called the *axon reflex* (Figure 30-1). Peripheral release of the neuropeptides SP and CGRP induces increased blood flow and edema, respectively, and gives rise to neurogenic inflammation.[40-43] This "injury free" inflammation can manifest as low levels of redness (flare) from increased blood flow and vasodilation, edema secondary to increased plasma extravasation, and nociception/pain after activation of additional nociceptive terminals.

Electric stimulation of a nerve at Aδ strength induces vasodilation, but not plasma extravasation, whereas stimulation at C fiber intensity results in both.[43] Importantly, in the absence of previous inflammation or direct activation of the immune system, immune cells do not infiltrate in response to nerve stimulation or intradermal SP.[44,45] However, reports have been made of mast cell degranulation after electrical nerve stimulation, indicating that neurogenic inflammation can activate these resident immune cells.[46] In addition, in joint synovium, peptidergic C fibers and sympathetic efferents have trophic effects on mast cell density, providing one specific avenue by which the CNS could influence neurogenic inflammation and other inflammatory states.[47]

One important aspect of neurogenic inflammation is that there is an active spinal cord contribution. Dorsal root rhizotomy eliminates sensory traffic between the spinal cord and the periphery while maintaining the integrity of the sympathetic nervous system and the peripheral terminal (Figure 30-2). Capsaicin activates the vanilloid receptor subtype 1 (TRPV1) expressed on peptide-containing C fibers, elicits a sensation of burning pain, and causes neurogenic inflammation. Significantly, rhizotomy of lumbar sensory roots reduces intradermal capsaicin-induced increases in blood flow and paw edema.[40,48-51] Loss of peptidergic C fibers, depletion of their neurotransmitters, or

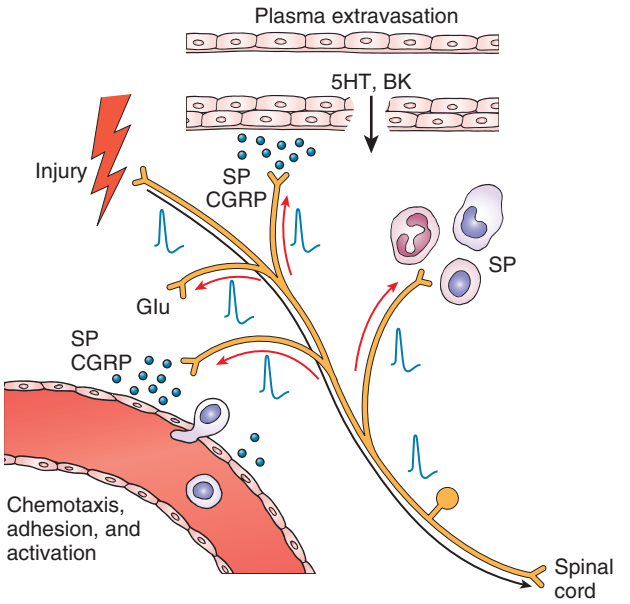

**Figure 30-1** The axon reflex is initiated by nociceptor activation in peripheral tissue by injury and inflammation. When noxious stimuli activate primary afferent fibers, action potentials (APs) are conveyed toward the spinal cord *(black arrows)*. However, at each fiber branch point, APs travel in every possible direction, including anterogradely *(red arrows)*. Thus antidromic axon reflexes are generated and induce peripheral release of neuropeptides. Neurotransmitter release signals to vascular endothelial cells to increase blood flow and induces plasma extravasation (leakage of vascular proteins, 5-hydroxytryptamine [5HT] and bradykinin [BK], and edema), which degranulates mast cells and activates other nerve fibers. Although the axon reflex by itself is not sufficient to recruit immune cells, in a primed system it facilitates recruitment of inflammatory leukocytes. Taken together, these actions produce the flare around an injury site. CGRP, Calcitonin gene–related peptide; Glu, glutamate; SP, substance P.

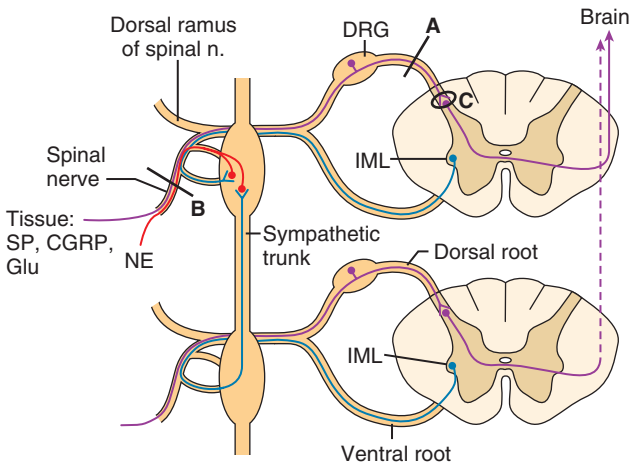

**Figure 30-2** Wiring diagrams of lesions used to assess pathways of neural control of inflammation. Cross-sections of two sequential segments of thoracic spinal cord are illustrated. At each level, a sensory neuron *(purple)*, sympathetic preganglionic neuron (*blue*, located in the intermediolateral cell column [IML]) and a sympathetic postganglionic fiber *(red)* are illustrated. Preganglionic fibers synapse in sympathetic ganglia at their entry level and also send collaterals to sympathetic ganglia along the chain. Dorsal rhizotomy (lesion A) severs only the sensory afferent fibers. Spinal nerve transection (lesion B) severs the sensory fibers and the efferent sympathetic postganglionic axons, including those innervating the vasculature. Intrathecal capsaicin destroys (bilaterally) the central terminals of the peptidergic C fiber (lesion C); importantly, the cell bodies in the dorsal root ganglia (DRG) and peripheral terminals are left intact. If capsaicin is given neonatally, all of the peptidergic fibers are lost. CGRP, Calcitonin gene–related peptide; Glu, glutamate; n., nerve; NE, norepinephrine; SP, substance P.

administration of SP-receptor antagonists also blocks or reduces neurogenic inflammation-induced vascular changes.

## Neurogenic Anti-Inflammation

A neurogenic component exacerbates the inflammation; however, efferent activity in the peripheral nerve also has anti-inflammatory influences. Under conditions of bacterial infection, complete Freund's adjuvant–induced inflammation, or the K/BxN mouse model of arthritis, nociceptors also release neuropeptides (CGRP, somatostatin, and galanin) that modulate draining lymph nodes and can reduce the amount of pro-inflammatory cytokines released by infiltrating macrophages. Somatostatin and galanin also inhibit peripheral release of sensory neuropeptides from peptidergic terminals and thus inhibit plasma extravasation.[52,53] Not surprisingly, animals with a genetic alteration that reduces nociceptor activity or animals with a loss of peptidergic C fibers have reduced pain behavior. Unexpectedly, under the inflammatory conditions previously noted, these animals display increased edema and immune cell infiltration and lymphadenopathy of the draining lymph node.[54-56] The decreased release of anti-inflammatory neuropeptides from the deleted or altered nociceptors could be responsible. Certainly, an anti-inflammatory role for somatostatin is reasonable because treatment with a long-lasting somatostatin analogue has been shown to elicit improvement in patients with refractory RA.[57] Factors controlling the final pro-inflammatory and anti-inflammatory balance of neurogenically released neurotransmitters remain undefined.

## Dorsal Root Reflex

The dorsal root reflex (DRR) is a strictly somatic positive feedback mechanism that engages neurogenic inflammation after intense peripheral activation of nociceptive afferent fibers (Figure 30-3A). Orthodromic action potentials in Aδ and C fibers arising from peripheral tissue activate ascending spinal nociceptive pathways and γ-aminobutyric acid (GABA)–containing inhibitory neurons within the spinal cord via glutamatergic linkages. The inhibitory neurons have collaterals synapsing on the central terminals of the Aδ and C fibers.[58,59] Low-frequency firing in this system elicits pre-synaptic inhibition and a decrease in spinal neurotransmitter release via a process known as primary afferent depolarization (PrAD).[60] In marked contrast, substantial tissue inflammation or injury leads to excessive PrAD and induces enhanced central release of GABA,[61,62] which results in generation of APs in afferent fibers that travel anterograde from the spinal cord to the injured tissue. Neurogenic inflammation triggered by the peripheral release of neurotransmitters, including glutamate, SP, and CGRP, then occurs.

Significantly, DRRs have been recorded in nerves contralateral to the initiating tissue insult.[63-65] This occurrence is consistent with the concept that inflammation in one limb results in inflammation on the mirror-image contralateral limb.[63,66,67] This appears to be a neuronal polysynaptic pathway, and it is not mediated by humoral factors.[66] Importantly, experimental monoarthritis can produce a cellular infiltrate and increased temperature that is specific to the

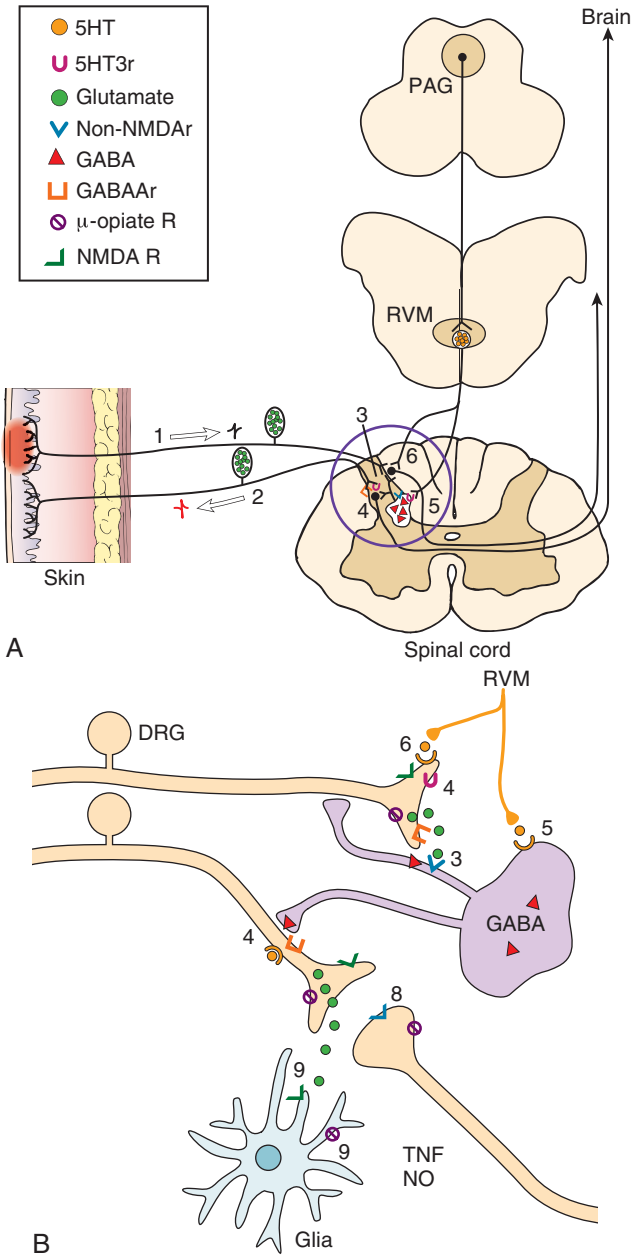

**Figure 30-3** **A,** The dorsal root reflex (DRR). A DRR is induced when (1) action potentials (APs) reach the spinal cord and then (2) anterograde propagation back to the tissue occurs. It is dependent on the central terminals of the afferent fibers being stimulated at an intensity that causes primary afferent depolarization (PrAD) at a level that exceeds action potential (AP) threshold. As pictured, the afferent action potential activates (3) a non–*N*-methyl-D-aspartate (NMDA) linkage on a γ-aminobutyric acid (GABA)ergic neuron. (4) Excess GABA acts on a $GABA_A$ receptor on the central terminal to elicit PrAD. Antagonism of GABA and/or non-NMDA receptors blocks DRR. (5) The system may also be triggered via 5-hydroxytryptamine (5HT) release from the raphe-spinal system acting on 5HT-3 receptors on the inhibitory interneuron or (6) on the terminal endings. **B,** Enlargement of inset in **A**. Activation of spinal opiate receptors and NMDA receptor antagonism is also effective in some longer-lasting models. These agents may work by (7) blocking pre-synaptic release of neurotransmitters, either by direct inhibition or removal of glutamatergic positive feedback. Alternatively, they can (8) act postsynaptically on pain transmission neurons or (9) by blocking glial activation and the resultant central release of pro-inflammatory agents such as nitric oxide (NO) and tumor necrosis factor (TNF). DRG, Dorsal root ganglia; PAG, periaqueductal gray; RVM, rostral ventromedial medulla.

mirror-image contralateral joint.[68] These studies also postulate a role for sympathetic efferent fibers on the noninjured side. Although anatomic details of this pathway remain undefined, DRRs along (group IV) C fibers leading to neurogenic inflammation provide one explanation of a final output pathway.

## Pain Transmission in the Dorsal Horn

The nociceptive sensory primary afferent fibers traverse from the peripheral tissue to the spinal dorsal horn, irrespective of their innervated structure. Not surprisingly, spinal nociceptive projection neurons reflect the local termination pattern of the primary afferents. Thus Aδ and C (groups III and IV) fibers project monosynaptically to superficial dorsal horn,[69-71] the area with the largest concentration of nociceptive-specific neurons. These neurons are subdivided into those having predominant input from Aδ or C fibers and convey information regarding sharp or burning pain, respectively.[72] The lateral deep dorsal horn (lamina V) receives nociceptive input from cutaneous and articular Aδ afferents[69] and also has low-threshold Aβ input. Neurons in this location predominantly have a wide dynamic range, meaning that they respond over the range from innocuous to nociceptive input but have higher-frequency firing in response to the higher-intensity stimulation. Pain projection neurons in the intermediate zone and central ventral horn have convergent input from muscle and cutaneous afferent fibers, including proprioceptors and nociceptors.[69]

Projection neurons receiving information concerning pain and inflammation convey this information to a wide variety of supraspinal structures. These neurons contribute to sensory discriminative, homeostatic, and affective components of pain, as well as to the autonomic responses resulting from the nociceptive stimuli. The classic spinothalamic tract (STT) projects to the ventral posterior lateral thalamus (VPL) and on to the somatosensory cortex. This pathway plays a prominent role in sensory discrimination of nociceptive stimuli. A second STT tract (only lamina I neurons) projects to the central portion of the medial thalamus (MDc) and then to the anterior cingulate, which contributes to the affective but not the sensory component of pain. A third STT pathway to the posterior portion of the ventral medial thalamus (VMpo) thalamus also receives an exclusive lamina I projection and projects rostrally to posterior insula, as well as to area 3a of the cortex. This area is thought to be the cortical processing area for homeostatic input, describing the extra-cellular milieu of the chemodetecting nociceptive C fibers and inflammatory pain, as well as some level of both sensory discrimination and affect.[73]

The spinomesencephalic and spinoreticular tracts project throughout the brain stem reticular formation. In addition to a strong lamina I contribution to the midbrain periaqueductal gray (PAG) and the surrounding parabrachial region, these two tracts provide some input from deeper spinal laminae. The parabrachial region has numerous two-way interconnections with autonomic control centers throughout the brain stem[74] and projects to limbic structures, including the amygdala. There is also a lamina I dorsal horn projection to medullary noradrenergic nuclei that integrate autonomic input and project back down to the preganglionic neurons of the intermediate horn, and thus participate in important sympathetic spino-bulbo-spinal feedback loops. Importantly, the vagal nucleus solitarius is also a termination site for lamina I neurons, thus involving the parasympathetic nervous system as well. Neurons in the deeper laminae (VII-VIII) have a strong bilateral projection to the brain stem (Figure 30-4A).

## Descending Modulation

Although in the early literature it was suggested that pain-selective descending modulation was exclusively inhibitory,[75] it is now appreciated that important excitatory descending pathways exist. As joint inflammation develops and activity in articular nociceptive afferents increases, descending inhibition to spinal nociceptive neurons increases in parallel.[76] This inhibitory feedback loop ameliorates the effects of ascending nociceptive activity. Under other conditions, positive feedback exacerbates it.[77] The backbone of the best-studied descending inhibitory modulation includes a linkage from the PAG to the spinal cord by way of the raphe nuclei, or via the brain stem noradrenergic nuclei (Figure 30-4B). The PAG processes indirect input from ascending pain pathways, the limbic system, and cortical pain-processing centers. Stimulation of ventrolateral PAG in animals and humans is strongly analgesic. The raphe nuclei have a prominent serotonergic projection to the superficial dorsal horn and, indeed, are the only source of dorsal horn serotonin. Serotonin (5-hydroxytryptamine [5HT]) released in the spinal cord can be anti-nociceptive if (1) inhibitory 5HT-1 or 5HT-2 receptors on pain projection neurons, such as in the spinothalamic tract, are involved or (2) if binding is to the excitatory 5HT-3 receptor found on GABAergic inhibitory interneurons or terminals of nociceptive afferents in the superficial dorsal horn.

Although activating an inhibitory pathway is analgesic, serotonin acting on 5HT-3 receptors is proalgesic because (1) in the presence of inflammation, additional 5HT-3 receptor activation of the inhibitory neuron acts just like excessive GABA and results in DRR generation, enhanced inflammation, and pain[63] and (2) some nociceptive projection neurons also have 5HT-3 receptors.[78] Enhanced pain associated with joint and tissue inflammation, but not with surgical incision, is subject to facilitatory influences from the raphe region.[79-81] The parallel PAG-spinal noradrenergic pathway has similar facilitatory and inhibitory feedback components. Inflammation in hairy but not glabrous skin is subject to an α2-adrenergic–mediated descending inhibition via this pathway.[82] Clinically, intrathecal administration of α2-adrenergic agonists produces analgesia. However, much like the receptor dichotomy seen for the serotonergic system, α1-adrenergic antagonists produce pain facilitation.

The amygdala is noteworthy not only because it appears to be important for pain processing but because of its unusual laterality. After induction of a unilateral monoarthritis, neurons in the right but not the left central nucleus of the amygdala develop increased nociceptive responses, irrespective of the site of inflammation.[83] Even more intriguingly, locally administered antagonists of second-messenger pathways to the right amygdala in animals with inflammation result in reduced/blocked enhanced pain behavior resulting from stimulation anywhere in the body.

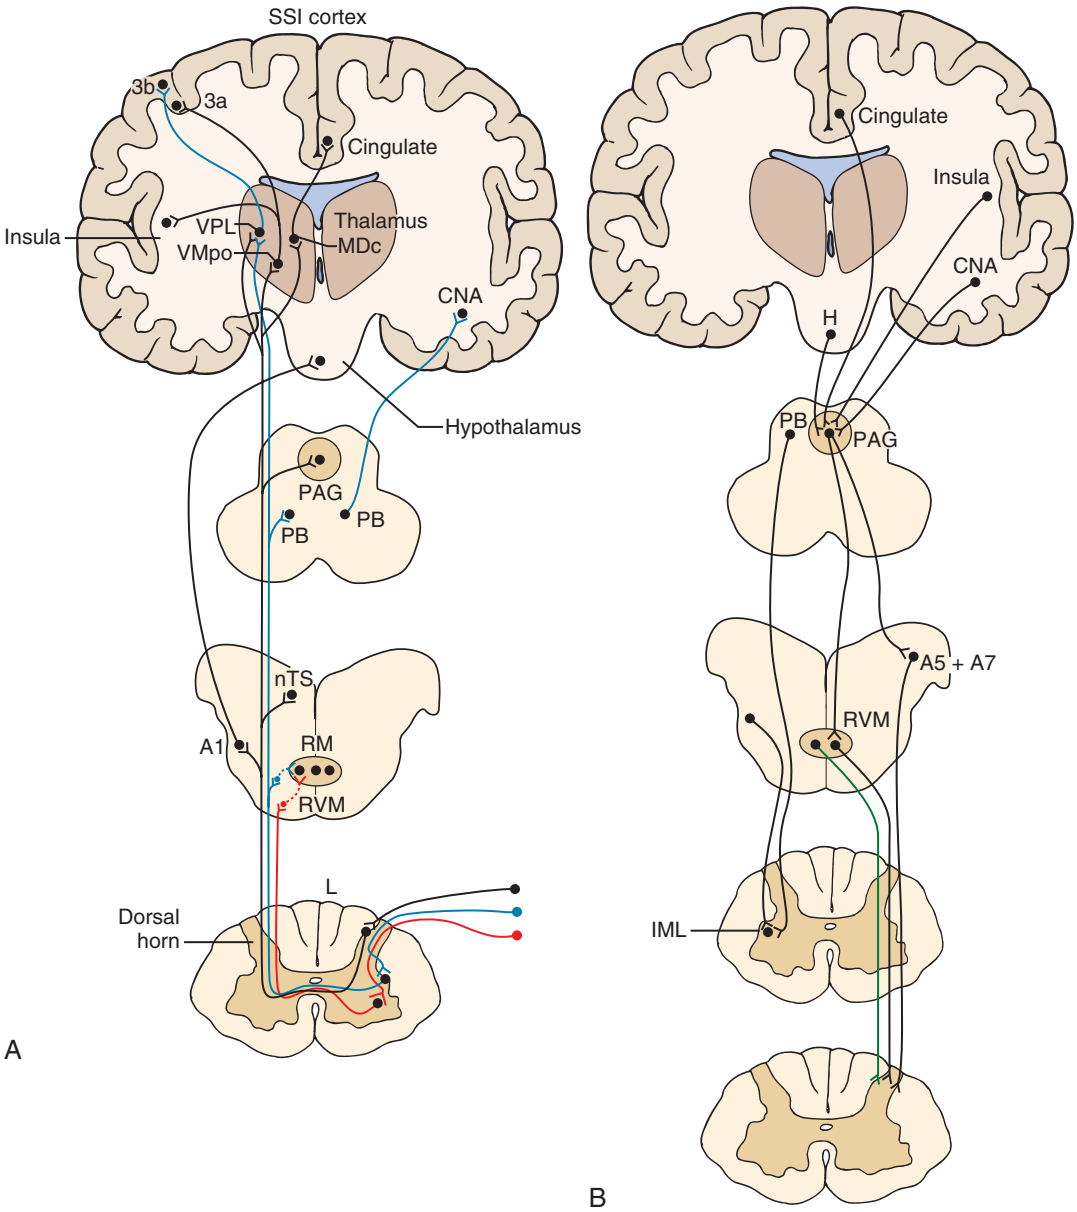

**Figure 30-4** **A,** Ascending pain pathways. Nociceptive afferent fibers enter the spinal cord through the dorsal root and activate neurons in laminae I *(black),* V *(blue)* and VII-VIII *(red)*. Lamina I neurons have strong monosynaptic C fiber input (slow, burning pain) and project directly to the vagal nuclei, periaqueductal gray (PAG), parabrachial nucleus (PB) and thalamic nuclei, mediodorsal thalamic nucleus (MDc) and posterior ventral medial nucleus (VMpo), with a weaker projection to ventral posterior thalamus (VPL). Importantly, the spinovagal connection is triggered by visceral but not cutaneous nociceptive stimulation. Lateral PAG projects onto the amygdala, whereas the VMpo projects further to the insula cortex and area 3a in the deep primary somatosensory cortex (SSI). Thus area 3a has predominantly C fiber input, perhaps accounting for its association with burning pain and inflammation. The MDc projects onto the cingulate gyrus (area 24c). There is also a lamina I projection to several of the catecholamine cell groups in the ventrolateral medulla, including the nucleus of solitary tract (nTS), and A1, a relay to the hypothalamus, which participates in nociceptive stimulation-induced release of adrenocorticotrophic hormone (ACTH). Lamina V-VIII neurons also project to the brain stem reticular formation and PAG and onto the VPL thalamus. Whereas all of the other spinal projections are primarily contralateral, the spinoreticular tract is bilateral (not illustrated). *Dotted lines* indicate indirect connections. **B,** Descending modulatory pathways. Several cortical areas project to the ventrolateral PAG, including the insula, cingulate, frontal lobe, and amygdala. There is also a prominent connection from the hypothalamus. PAG, in turn, projects to several of the noradrenergic brain stem nuclei (including A5 and A7) and to nuclei of the rostral ventral medulla (RVM). Importantly, these RVM neurons contain substance P and other neurotransmitters, as well as serotonin, and wield bidirectional (excitatory and inhibitory) control over ascending pain impulses. Descending control over preganglionic neurons in the intermediolateral cell column (IML) come from the lateral PB and ventrolateral medulla. CNA, Central nucleus of the amygdala; H, hypothalamus; L, lumbar.

## NEURONAL REGULATION OF INFLAMMATION IN ACUTE INFLAMMATORY MODELS

Acute inflammation can be induced by injection of kaolin and carrageenan into the knee joint. In this model, DRRs were recorded from group II, III, and IV fibers, indicating that they are generated in the large myelinated (group II) fibers, as well as the finely myelinated and unmyelinated nociceptive afferents.[84] If acute inflammation has a DRR component, then spinal blockade of either the glutamate receptor (non-*N*-methyl-D-aspartate [non-NMDA]) on the spinal inhibitory neuron or antagonism of the pre-synaptic $GABA_A$ receptor located on the central terminal of the nociceptive afferent fiber should reduce DRR reflexes and peripheral signs of inflammation.

Pre-treatment with either of these agents is effective in blocking not only the actual anterogradely transmitting DRRs[85] but also in reducing edema and temperature increase in the inflamed joint or tissue and pain behavior referred to the paw.[86-88] NMDA or $GABA_B$ receptor antagonists are without effect. These data are consistent with involvement of the DRR originating in the articular afferents, as previously outlined. These data argue against a requirement for activated spinal glia, whose activation is more closely linked to NMDA receptor–mediated spinal sensitization, playing a prominent role in this reflexive activity. Unexpectedly, spinal post-treatment with the non-NMDA and $GABA_A$ antagonists partially reversed already established knee joint swelling but did not reduce the elevated joint temperature,[86] indicating perhaps that different aspects of the inflammation are under separate controls and that, even in acute models, these paradigms change after initiation of the inflammation.

Experiments were repeated with use of capsaicin injection into the skin rather than co-injection of kaolin and carrageenan into the joint. Capsaicin also induced anterograde DRRs in Aδ and C fibers, but unlike the joint afferents, not in Aβ fibers.[89,90] Pre- and post-treatment with spinal $GABA_A$ and non-NMDA glutamate receptor antagonists was effective in this model, but in contrast to the previous paradigm, spinal NMDA receptor antagonists also blocked the enhanced DRRs, as well as reducing the surrounding flare and edema.[90] It is not known if NMDA receptor dependence is due to the location of the insult (joint vs. skin) or to another variant in the experimental design.

The anatomic substrate of the DRR theory requires involvement of sensory fibers running through the dorsal root for both the afferent and efferent legs of the reflex in addition to spinal inhibitory neurons. Theoretically, it does not require the autonomic nervous system, supraspinal centers, or the adrenohypothalamic axis. Both DRRs and edema in the acute inflammatory phase of the kaolin/carrageenan model are not blocked by surgical sympathectomy or high spinal cord transection but are readily interrupted by rhizotomy, lidocaine application to the peripheral nerve, or nerve crush.[91,92] However, reduction in peripheral inflammation due to the functional loss of primary afferent fibers does not indicate whether the nerve fibers are a necessary part of the afferent, the efferent, or both legs of the reflex. A corollary to the need for GABA release from the inhibitory interneuron for DRRs is that anything that activates the interneuron will increase neurogenic inflammation and factors that inhibit inhibitory interneuron decrease the peripheral effect. As previously stated, serotonin, acting on postsynaptic 5HT-3 receptors on the interneuron, facilitates GABA release.[93] Thus, although supraspinal circuitry is not necessary for DRR-induced neurogenic inflammation, activation of either the PAG or the raphe nuclei enhances the phenomena.[63,94]

Another model of acute knee inflammation induced by injection of lipopolysaccharide (LPS) into a knee joint previously primed with carrageenan generates a reactive monoarthritis with leukocyte infiltration into synovial fluid and joint swelling as indices of inflammation. This model is fundamentally different from the previous kaolin/carrageenan one in that spinal administration of glial inhibitors prevented signs of inflammation.[95] This outcome is consistent with the observed dependence of joint damage and inflammation on NMDA receptor activation.[96]

Pre-treatment with spinal tumor necrosis factor (TNF) antagonists or neutralizing antibody also reduced vascular leakage into the knee and infiltration of polymorphonuclear leukocytes into the synovial fluid.[95,97] A spinal PrAD inhibitor (furosemide) also successfully blocked signs of peripheral inflammation in this model.[95] Co-administration of furosemide with either glial inhibitor did not produce an additive effect, indicating, perhaps, that they are in series within a common pathway. Thus, in this third intermediate duration model, DRRs are linked to spinal modulation of peripheral inflammation in tandem with a requirement for glial activation. These results were unaffected by corticosteroid synthesis inhibitors, indicating a lack of participation of the hypothalamic-pituitary-adrenal (HPA) axis.

Spinal administration of morphine also prevented knee swelling and preserved joint integrity in the monoarthritis model with a nonsignificant trend toward fewer immune cells infiltrating into the joint space.[96] The opiate could be acting via (1) pre-synaptic inhibition of the nociceptive afferent signal, reduction of afferent transmitter release and blockade of GABAergic interneuron activation, GABA release, and the DRR or (2) by postsynaptic inhibition of glia or neurons along the nociceptive transmission pathway. Activated glia release TNF and nitric oxide (NO) and further drive and sensitize the system (Figure 30-3B).

In a fourth type of model, cutaneous acute inflammation was induced by intradermal or subcutaneous injection of paw carrageenan, and either vascular leakage (edema) or neutrophil infiltration was measured. Intrathecal pretreatment with a nonsteroidal anti-inflammatory drug, morphine, or agents that inhibit the NO/cyclic guanosine monophosphate (cGMP) pathway all blocked edema without reducing neutrophil infiltration.[98,99] Mechanistically, these agents collectively reduce spinal neurotransmitter release from excited nociceptors. In similar experiments, spinal pre-treatment with either 5HT-1 receptor agonists or 5HT-2 receptor antagonists reduced paw swelling.[98,100] This outcome would fit with a blockade of DRRs, but not of other elements, that elicit immune cell chemotaxis.

In marked contrast, spinal administration of adenosine A1–specific (A1) but not adenosine A2–specific (A2) agonists inhibited neutrophil accumulation due to intradermal carrageenan.[101,102] The adenosine effect was mimicked by a spinal NMDA antagonist and reversed by spinal NMDA

agonists. This latter experiment demonstrated that the NMDA linkage is downstream of the adenosine effect.[44] Inhibition of cellular infiltrates highlight that the spinal A1 protective effect goes beyond merely blocking the DRRs through direct inhibition of the spinal terminals. Interestingly, paw carrageenan elicits a massive reduction in peripheral adenosine, which is time linked to neutrophil infiltration. Adenosine loss, as well as the increase in neutrophil accumulation, is blocked by spinal pre-treatment with an NMDA antagonist.

Peripheral adenosine acting on A2 receptors inhibits peripheral neutrophil infiltration,[103,104] and thus maintenance of peripheral adenosine is thought to be the basis of the antiallodynic activity of both the spinal adenosine A1 agonists and NMDA receptor antagonists.[101] Surprisingly, although both SP and TNF increased in the inflamed skin, neither spinal adenosine A1 agonists nor NMDA antagonists affected these substances in this acute model. Spinal adenosine A1–mediated modulation of inflammation is also dependent on an intact dorsal root (sensory fibers) but is not dependent on the sympathetic efferent fibers.[102] Unlike the other cutaneous models, intradermal carrageenan-induced inflammation was not affected by spinal inhibition of non-NMDA glutamatergic receptors or by functional elimination of capsaicin-sensitive C fibers.

## NEURONAL REGULATION OF INFLAMMATION IN CHRONIC MODELS OF INFLAMMATION

Animal models with joint inflammation that lasts for weeks or more are used to study spinal cord control of peripheral inflammation in RA and include adjuvant-induced arthritis (AIA) in rats, antigen-induced arthritis (AA) in mice, and collagen-induced arthritis (CIA) in mice. As with the acute inflammatory models, section of major lumbar nerve trunks greatly diminished the development of inflammation in the denervated limb.[105,106]

Upon first contact with locally injected capsaicin, afferent neurons discharge action potentials, which in turn evokes burning pain. Higher doses or repeated application of capsaicin desensitizes sensory neurons, and eventually nerve conduction through the treated segment is selectively blocked in capsaicin-sensitive (some peptidergic C) fibers. When capsaicin is injected at high doses intrathecally, it leads to destruction of axon terminals in the primary afferent terminal regions of the spinal cord (see Figure 30-2). Systemic capsaicin administration to neonatal rats destroys subpopulations of DRG cells, reflected by loss of SP and CGRP immunoreactivity and sensory deficits. When intrathecal or systemic neonatal capsaicin pre-treatment was used to eliminate only the central peptidergic sensory fibers, or both their central and peripheral terminals, respectively, severity of the inflammation in the AIA model was consistently ameliorated, indicating that this subpopulation of sensory afferent fibers, and presumably some element that they activate in the spinal cord, contributes to the inflammation.[66,107-109] Interestingly, capsaicin pre-treatment, at doses sufficient to reduce sensory activity, also reduced AIA-induced T cell infiltration into the synovium.[107]

For unclear reasons, lumbar dorsal rhizotomy prior to induction of AIA decreased the time to presentation of clinical signs in limbs innervated by sectioned nerve roots.[66] The commonality among the three lesions is loss of the peptidergic afferent fiber connection. Both capsaicin and rhizotomy preserve the sympathetic efferent fibers. Although there is a loss of the entire peptidergic fiber after systemic neonatal capsaicin, it is thought that both rhizotomy and intrathecal capsaicin preserve all of the DRGs and peripheral peptidergic fibers.[110] Additionally, motor function is preserved after rhizotomy and capsaicin (see Figure 30-2). Interestingly, in a combined lesion study in which animals were pretreated with capsaicin (bilaterally) in conjunction with a unilateral rhizotomy, the joint injury was reduced on the capsaicin-only side, whereas the lesion-plus-capsaicin side displayed increased disease severity.[66] These results show that the effect of peripheral denervation on the severity of joint inflammation in the rat is not dependent only on loss of a particular subset of neurons but rather reflects changes in the activity of both afferent and efferent peripheral neurons. In addition to the complexity of the wiring, it is necessary to involve additional autonomic and endocrine feedback loops to explain the system.

In accordance with the effect of spinal A1 adenosine (Ado) receptor agonists on dermal neutrophil infiltration in an acute inflammation model, continuous spinal administration of an adenosine A1 receptor agonist greatly ameliorated AIA severity. Spinal treatment was beneficial even if it was started as late as 8 days after immunization when animals first presented with clinical signs, but it had a much smaller, nonsignificant effect on paw swelling when the course of treatment began after clinical signs were well established (day 14).[111] Noxious stimulation of afferent fibers results in an increase in c-Fos expression in the nuclei of neurons in the spinal dorsal horn, which is thought to reflect increased neuronal activity levels.[112] Despite the more than 80% decrease in AIA-induced presentation of clinical signs observed with intrathecal adenosine A1 agonist treatment, simultaneous reduction of the AIA-induced c-Fos expression in the superficial dorsal horn was only 22%.[111]

Reduction of c-Fos expression in other spinal laminae was not affected by the A1 agonist. Taken together, this implies that pain is only marginally reduced by the spinal adenosine agonist. Similar anti-inflammatory results were observed with either intrathecal administration of a TNF-neutralizing antibody or SB203580, a p38 mitogen-activated protein kinase (MAPK) inhibitor. In addition, these agents also suppressed synovial infiltration of immune cells and expression of the pro-inflammatory cytokines interleukin (IL)-1β, IL-6, and TNF and matrix metalloproteinase (MMP)-3.[113,114]

Arthritis induces a relative increase in sympathetic tone compared to tone of the parasympathetic nervous system; these changes in tone are also prevented by blocking the effects of spinal TNF.[114] Continuous spinal administration of morphine or the NMDA antagonist ketamine throughout a 3-week course of AIA caused a major decrease in joint swelling and synovial infiltration of inflammatory cells.[96] This outcome is likely the result of a loss of DRRs due to pre-synaptic actions on μ-opioid and NMDA receptors, respectively. The opioid-associated reduction in swelling was maintained over the entire period, and tolerance did not develop.

## SYMPATHETIC EFFECTS ON PERIPHERAL INFLAMMATION ARE TIME DEPENDENT

When activated, most sympathetic postganglionic neurons release norepinephrine, which activates adrenergic receptors expressed on the peripheral target tissue. There are two adrenergic receptor types (α and β) that have several receptor subtypes (α1, α2, α3, β1, and β2). Cells in the innate immune system appear to express α1, α2, and β2 receptors, whereas those of the adaptive immune system primarily express the β2 subtype.[4] Importantly, stimulation of the receptor subtypes can elicit different functional effects. For example, macrophages are activated through α2-receptor stimulation, whereas β2-receptor stimulation has a suppressive effect.[4] Thus the role of the sympathetic nervous system in immune cell functioning is complex, and directed pharmacologic studies show mixed results in animal models of arthritis, both ameliorating and exacerbating disease severity. It has been suggested that during the early phase of inflammation, there is "a shift in the autonomic balance toward a sympathetically dominated state."[114]

Neuroactive agents are released from the sympathetic terminals, which contribute to increases in joint and tissue swelling. Mechanisms can vary from increases in blood flow to redistribution, migration, and chemotaxis of leukocytes toward the site of inflammation and β2-mediated release of interleukins and other algesic agents from resident keratinocytes.[115,116] Thus conflicting data with regard to the effect of adrenergic drugs might, in part, be explained by timing of treatments relative to arthritis induction and the onset of disease.

Sympathectomy prior to or at induction of AIA, CIA, and AA, with a loss of the sympathetic terminals in the inflamed joint, results in amelioration of bone damage and a delay in onset of the clinical arthritis.[66,117-119] In contrast, when the sympathetic nervous system was interrupted after the early phases of inflammation, it either did not alter joint swelling and histopathologic scores or exacerbated the disease.[118-121] These studies suggest that the sympathetic nervous system has immunomodulating effects in arthritis models: Prior to the immunization phase or at the early stage of inflammation, it has pro-inflammatory effects, and after the onset, it may have anti-inflammatory effects. This change may be due to a functional loss of sympathetic innervation of the inflamed tissue over time; this loss has been observed in patients with RA and in animal models of RA.[116,122,123] Indeed, an inverse relationship exists between tyrosine hydroxylase (TH)–positive nerve fibers (a catecholaminergic marker of sympathetic neurons) and both the inflammation index and levels of released IL-6 in synovial tissue of patients with RA.[124] This reduction in adrenergic nerve endings is specific and may be due to increased secretion of mediators of sympathetic axon repulsion, such as semaphorin 3c; peptidergic sensory nerve fibers are not affected.[125]

The biphasic nature of the sympathetic system is most prominent in polyarthritis models where swelling and inflammatory signs are present throughout the full duration of the experiment, usually about 2 months. In the acute monoarthritis model mentioned previously, joint swelling presents on day 1 and resolves in 7 to 10 days.[119] As in the polyarthritis model, sympathectomy prior to swelling presentation in the monoarthritis model ameliorated the disease, and post-treatment had no effect. However, if a second flare is induced by a second injection of antigen into the joint after the first flare has resolved, preinjection sympathectomy is once again effective. This outcome implies that in this model and, perhaps, in clinical RA, the sympathetic terminals return and become functional between flares.

Examination of adrenergic receptor subtypes in more detail suggests a prominent role for β2-adrenergic receptors in the sympathetic nervous system's time-dependent, immunomodulatory effect. Rats with continuous administration of a catecholamine reuptake inhibitor or a β2-adrenergic receptor antagonist that began prior to disease induction showed a delayed presentation of clinical signs and less severe joint damage than did control subjects.[126] Smaller, yet significant, protective effects of these agents on joint injury were obtained when treatment was confined to the period either before or after presentation of clinical disease, indicating that reduction of endogenous catecholamines was beneficial throughout the entire 28-day time course.

Subsequent studies from other groups have confirmed the role of early systemic β2-receptor activation as contributory to joint damage and report that administration of β2-agonists at or shortly after disease onset increased the severity of the disease.[120] In vivo studies on the function of α-adrenergic receptor subtypes in experimental arthritis have shown that administration of a nonselective α1/2 antagonist prior to immunization had no effect, whereas administration at the time of immunization increased severity and at the time of disease onset reduced severity.[120,126] Administration of an α1- or α2-selective antagonist prior to immunization had no effect.[126,127] When administered prior to immunization, α2-selective agonists reduced arthritis severity.[128] Thus, the significance of different adrenergic receptor subtypes at different times is unclear, although it seems that both α- and β-adrenergic receptors contribute to inflammation. Beyond these adrenergic-dependent mechanisms are adrenergic-independent components of the inflammation. Local production of inflammatory agents such as bradykinin act directly on sympathetic terminal varicosities to release prostaglandins and adenosine.[129] Many of the complexities concerning sympathetic effects arise from the fact that both adenosine and norepinephrine have concentration-dependent preferences for different receptor subtypes. Different outcomes (pro-inflammatory or anti-inflammatory) result from the subtypes activated.

## PARASYMPATHETIC EFFECTS ON PERIPHERAL INFLAMMATION

Parasympathetic, preganglionic neurons are found in the brain stem and in the caudal spinal cord (S2 through S4 segments). The vagus nerve is the main parasympathetic interface between the brain and body. One body of evidence indicates that vagal stimulation dampens inflammation via activation of a homeostatic "cholinergic anti-inflammatory reflex."[130] The hypothesis is that activation of high-threshold sensory and/or vagal afferents in response to peripheral inflammation provides input to the vagal nuclei in the brain stem and subsequent activation of parasympathetic efferent

pathways. This process culminates in peripheral release of acetylcholine (ACh), which binds to nicotinic ACh receptor subunit 7 (α7nAChR) expressed on immune cells. However, the exact anti-inflammatory efferent linkage is uncertain, and questions remain to be answered. One model suggests that the efferent vagus nerve signals to the celiac plexus and activates the splenic nerve, resulting in local release of norepinephrine. Norepinephrine activates splenic T cells, which promotes local production and release of ACh that acts on macrophages and other immune cells and suppresses cytokine release (Figure 30-5A). However, details of this efferent anti-inflammatory pathway are still a matter of debate. The vagus nerve does not innervate lymphoid tissues, and it has been questioned whether vagal efferents have functional connections to the splenic nerve in the celiac plexus.[4,131]

An alternative explanation is that the vagus nerve has an as yet unidentified target, where it stimulates and mobilizes ACh-synthesizing T cells in lymphoid tissues. Once mobilized, a subset of these T cells is sequestered in the spleen. In this hypothesis, ACh activates α7nAChR on the peripheral terminals of the splenic sympathetic nerves, resulting in noradrenaline release, which then acts on β-adrenergic receptors on splenic macrophages to suppress their production of cytokines[131] (Figure 30-5B). Of note, afferent nerve signals also activate the HPA axis, which promotes glucocorticoid release from the adrenal glands (Figure 30-5).

Vagal involvement has been extensively studied in experimental colitis and endotoxemia models, but several studies have demonstrated effects in animal models of peripheral inflammation. Injection of CNI-1493, a pro-inflammatory mediator synthesis inhibitor, into the cerebral ventricles 1 hour before injection of carrageenan into the paw prevented the expected edema. This anti-inflammatory effect is mimicked by vagal stimulation and attenuated by either bilateral cervical vagotomy or by systemic atropine, thus solidly implicating the vagus nerve.[132,133] Similar benefits of vagal stimulation were observed in CIA (decreased edema, pannus formation, and bone erosion).[134] Systemic treatment with nicotine or an α7nAChR-specific agonist also ameliorated disease activity, whereas unilateral cervical vagotomy exacerbated disease severity.[135] In addition, α7-deficient mice showed a marked increase in synovial inflammation compared with wild-type littermates.[136] Vagal stimulation or direct activation of α7nAChR inhibits inflammasome activation[137] and release of extra-cellular high mobility group box-1 (HMGB1),[138] which has been linked to joint disease in persons with CIA.[139] Interestingly, intrathecal administration of the p38 MAPK inhibitor SB203580 acutely increases vagal outflow and the resultant peripheral cholinergic activity.[140] It is possible that the joint protection offered by p38 MAPK inhibition in arthritic animals is due to increased vagal outflow rather than decreased DRR activity.

## ROLE OF PAIN IN INFLAMMATORY DISEASE

The impact of CNS activation in regulation of inflammation may not be inherently obvious. In addition to generating pain sensations, activation of nociceptors leads to local axon reflexes that cause release of neurotransmitters from peripheral sensory nerve terminals. This mechanism regulates not only small blood vessels but also chemotaxis and activation of immune cells, mainly in a pro-inflammatory fashion, and importantly, it is spatially confined. Activation of nociceptors can also generate dorsal root reflexes, which, in addition to driving neurogenic inflammation at the site of peripheral stimulation, can cause similar responses on the mirror image body site. In contrast, autonomic stimulation has both localized and systemic effects on immunity.

Sympathetic outflow might affect the inflammatory process in specific sympathetically innervated tissue or have a more general impact by driving systemic release of catecholamines from adrenal medulla and thus affect immune cells, or it can modulate immune organs that are innervated by sympathetic efferents, such as lymph nodes and spleen. Although linkages delineating the vagal anti-inflammatory pathway are still being defined, evidence for a parasympathetic influence on the immune system is strong and points to non-neuronal linkages between vagal efferents and the effector site. It is becoming clear that somatosensory and autonomic neuroimmune interactions are much more intricate than previously thought. Furthermore, it is quite likely that it is not individual neural processes and molecules but rather specific combinations of activating and suppressing neuronal signaling that influence different stages and types of immune responses.

Currently, preventing or reducing the activity in the sensory nervous system is a therapeutic target, primarily when it comes to controlling pain as a symptom. However, because activation of nociceptors drives neuronal release of factors that trigger neurogenic inflammation, treatment of immune disorders may therefore need to include targeting of nociceptors, as well as of immune cells. Thus an increased understanding of the molecular interplay between the sensory nervous system and the immune system and the ability to regulate excitability of sensory neurons may have important therapeutic consequences in a number of diseases, including (but not limited to) migraine, arthritis, asthma, and inflammatory bowel disease.

The role of the autonomic nervous system in immunoregulation has led to the proposal of new anti-inflammatory therapeutic approaches for chronic inflammatory conditions. Based on the animal models previously discussed, it can be envisioned that regulating the activity in the sympathetic or parasympathetic nervous system can control inflammation. No clinical study of adrenergic agents as a treatment strategy for patients with chronic inflammatory joint disease has been published. Because data targeting adrenergic receptors obtained from animal models are somewhat variable, additional research is needed to fully understand how catecholamines influence the functional state of specific immune cell populations; without that information, it is difficult to draw definitive conclusions as to which treatment would be beneficial for which patient groups.

With regard to the parasympathetic nervous system and treatment, the two major options are pharmacologic activation of the α7nAChR or vagal stimulation. Nicotine is a potent α7nAChR agonist, but the therapeutic value of nicotine is limited because of its lack of specificity and toxicity. More specific α7nAChR agonists are well tolerated in healthy volunteers and in patients with schizophrenia.[141,142] However, the LPS-induced innate immune

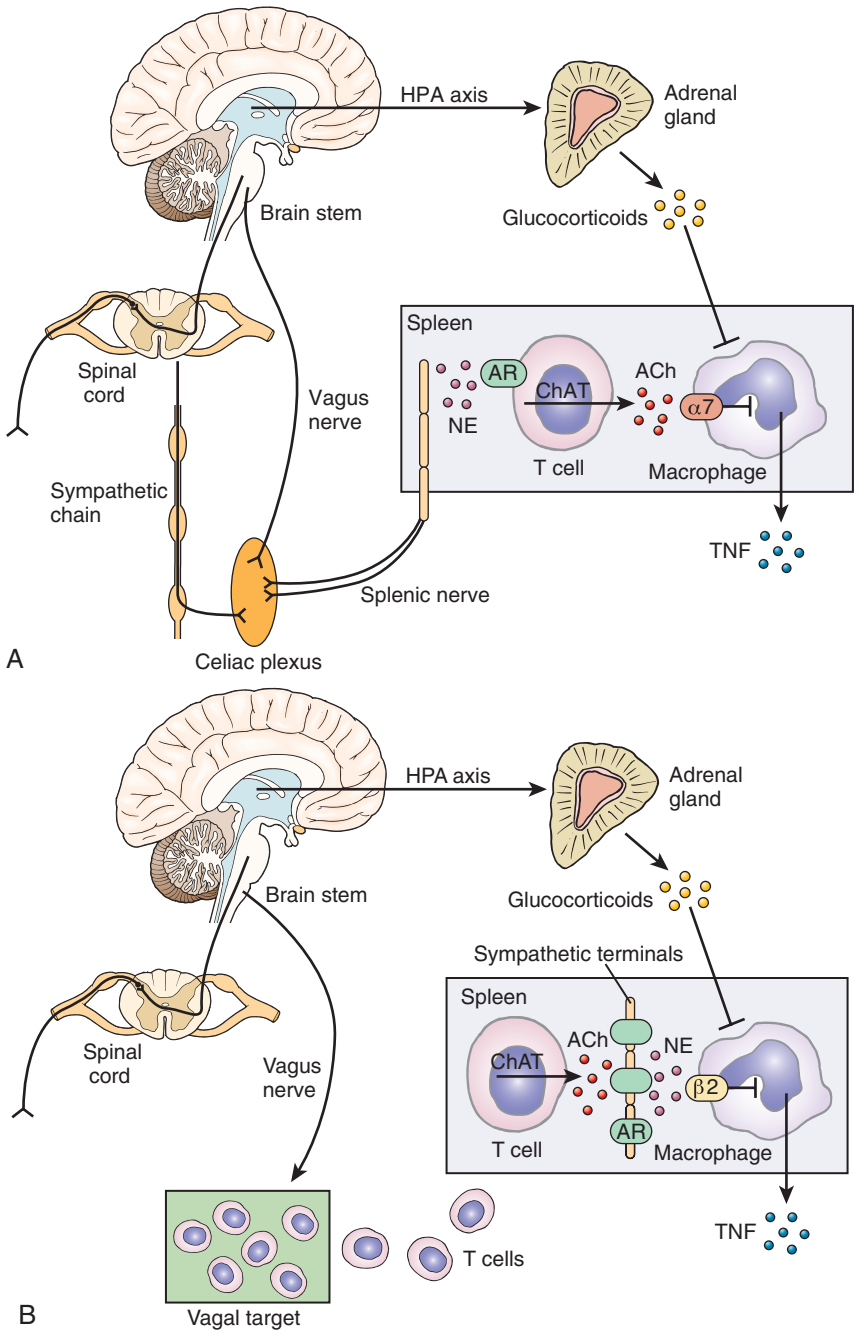

**Figure 30-5** Stimulation of the efferent vagus nerve inhibits tumor necrosis factor (TNF) production in the spleen. The illustrations depict two models for this anti-inflammatory pathway. **A,** Stimulation of the efferent arm of the vagus nerve signals to the celiac plexus, where the splenic nerve is activated. The splenic nerve releases norepinephrine (NE) in the spleen, which activates adrenergic receptors (AR) on choline acetyltransferase (ChAT)-positive T cells. T cells then produce and release acetylcholine (ACh), which acts on α7nACh receptors (α7) on macrophages and other immune cells and suppresses cytokine release. **B,** This model is based on the absence of a direct neuronal link from the vagus to the spleen and suggests a non-neural connection. The vagus nerve targets a (as yet unidentified) structure, where it is in close contact with ChAT-positive T cells, which are mobilized and sequestered in the spleen. ACh released by the T cells activates α7nAChR on the peripheral terminals of the splenic sympathetic nerves, which release norepinephrine. Norepinephrine then acts on β-adrenergic receptors on macrophages and suppresses their production of TNF. Last, following sensory input to the brain stem, the signals are also relayed to the nuclei controling the function of the hypothalamic-pituitary-adrenal (HPA) axis. This results in an increased release of glucocorticoids from the adrenal gland, also connecting the networks to humoral anti-inflammatory mechanisms.

response (release of TNF, IL-6, IL-10, and IL-1 receptor antagonist) in humans was not reduced by the highest tolerable dose of GST-21, an α7nAChR agonist, compared with placebo.[143] Ongoing studies exploring the potential of vagal nerve stimulation in patients with RA are under way. Vagal stimulation is already in use clinically for treatment of refractory epilepsy and depression.[144,145] Intriguingly, long-term vagal stimulation in patients with epilepsy caused a normalization of plasma cytokines and cortisol levels compared with the control group.[146] However, further preclinical and clinical studies are needed to further explore the potential and safety of using vagal stimulation as therapy for patients with inflammatory disorders.

CHAPTER 31

# Clinical Research Methods in Rheumatic Disease

Yvonne M. Golightly • Joanne M. Jordan • Kenneth G. Saag

**KEY POINTS**

- Epidemiology is the study of the distribution of disease and its determinants in populations. Epidemiologic methods can be used to describe the frequency or development of disease and to determine underlying risk factors.
- Prevalence is the frequency of disease in the population at a given time, including both existing and new cases. Incidence measures the development of disease with time in an initially disease-free population.
- The odds ratio (OR) compares the odds of disease in an exposed population to that in a population without the exposure or risk factor under study. The relative risk (RR) is the risk of development of disease with time in an exposed population compared with an unexposed population. In instances in which the disease is rare, the OR can estimate the RR.
- Threats to the validity of a study include chance, systematic bias, and confounding. Confounding occurs when an extraneous factor, associated with both the exposure of interest and the disease, but which is not part of the causal pathway between exposure and disease, is superimposed on the true risk factor/disease relationship.
- Case-control studies examine exposures in a population that already has the disease, and compares them with exposures in otherwise comparable but disease-free individuals derived from the same source population. This study design may be subject to recall bias, in which individuals with disease are more likely to recall exposure to risk factors than those without the disease, but it may be the design of choice for rare diseases.
- Cohort studies follow groups of individuals with and without an exposure of interest to measure the development of disease with time. Because the exposure assessment precedes the disease, time can help determine causation.
- Randomized controlled trials (RCTs) most closely resemble formal experiments in which the exposure is manipulated by the investigator and the response upon disease is compared between groups that receive the active intervention and those that receive a placebo or other comparator. A pragmatic clinical trial provides evidence of real world effectiveness.

Epidemiology is the study of the distribution of disease and its determinants in populations.[1] Its purpose is to describe the frequency of disease and to determine risk factors and causes responsible for variation in disease occurrence. Comparison of the relative strengths of risk factors and assessment of their generalizability can allow truth to be inferred to a broader population. Causality is often difficult to discern in observational investigations, particularly based on the results from a single study. The criteria proposed to assess the likelihood of a cause-effect relationship include consideration of the strength of the association, biologic credibility, consistency with other investigations, the temporal sequence, and a dose-response relationship.[2] This chapter will explain basic epidemiologic concepts and definitions; describe the major study designs, their strengths and weaknesses, and their usefulness in inferring causality; and demonstrate specific applications of these principles to the study of rheumatic diseases. The term "disease" will be used to represent a disease, death, or other health outcome of interest, and the term "exposure" will be used to represent a risk or protective factor examined for its association with disease.

## MEASURES OF DISEASE OCCURRENCE

The frequency of a disease in a population at any given time is referred to as its *prevalence*. Measured at one point in time, prevalence is the proportion of individuals with a disease of the total population under study. Importantly, the numerator makes no distinction between new and established cases of disease. Multiple estimates of disease prevalence during a period of time are commonly used to determine trends in disease occurrence or the need for health services.

### Incidence

To determine the likelihood that disease will develop with time, repeated observations of the same people are required to determine in whom disease develops and in whom it does not. Incidence proportion, or risk, is the frequency of new cases during a specified time, out of those at risk for, but without, the disease at baseline. During the observation period, a person may manifest the disease in question, die

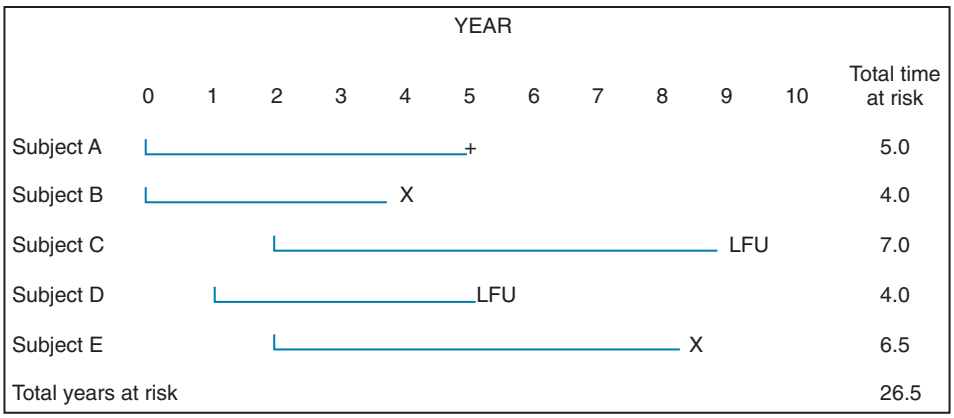

**Figure 31-1** Hypothetical calculation of person-time at risk for study of incidence of systemic lupus erythematosus during 10 years. |, Beginning of observation period; LFU, lost-to-follow-up; +, died; X, developed disease.

from competing risks, or be lost to follow up. All of these situations result in that person no longer contributing time at risk to the denominator. The concept of person-time includes the actual time at risk contributed by each individual. For example, consider the hypothetical example of incidence of systemic lupus erythematosus (SLE) during a 10-year period (Figure 31-1). The disease may not develop in Person A during the observation period, but he or she may die at year 5 of a competing cause; this person contributes 5 person years to the denominator. SLE might develop in Person B 4 years after the study begins, when he or she is thus no longer at risk; this person contributes 4 person years of time at risk to the denominator. Person C joins the study at year 2 and is lost to follow-up at year 9, contributing 7 years of time at risk. Person D joins the study at year 1 and is lost to follow-up at year 5, for a total of 4 years of person time at risk. Person E joins the study at Year 2 and manifests SLE halfway between year 8 and year 9, contributing 6.5 person years at risk. Incidence rate is defined by the following[2]:

$$\text{Incidence rate} = \frac{\text{new cases developing during time period of observation}}{\text{total person-time at risk for each individual without the disease at study entry}}$$

In the example, two new cases of SLE are observed and the total person time from persons A through E at risk equals 5.0 + 4.0 + 7.0 + 4.0 + 6.5 = 26.5 person years. Thus, the incidence rate is 2 cases per 26.5 person years, or 1 case per 13.25 person years. This may be expressed as 0.0754 cases per person year or 7.54 cases per 100 person years.

## MEASURES OF EFFECT

The association between the disease and exposures or risk factors is more important than the description of the frequency of disease or its development. One way to examine this association is to compare the prevalence or incidence of disease in groups with a given exposure with those without that exposure. To assess the potential exposure/disease association, it is critical that the exposed and unexposed groups are comparable. Measures to delineate this relationship between disease occurrence and exposure vary according to study design. Cross-sectional surveys and case-control studies utilize the odds ratio (OR), which is a measure of the odds (prevalence odds = prevalence / 1-prevalence; incidence odds = incidence / 1-incidence) of disease in the exposed group compared with the unexposed group. Longitudinal designs can calculate a RR (ratio of risks) of the incidence of disease in the exposed compared with the unexposed groups.

## CLINICAL RESEARCH STUDY DESIGNS

Clinical research study designs include ecological studies, cross-sectional surveys, case-control studies, cohort studies, and randomized controlled clinical trials. The latter is frequently considered the most rigorous study design and the one most closely representing a formal experiment. Each study design has its own inherent strengths and weaknesses (Table 31-1), and the choice of study design depends upon the research question, the rarity of the disease under study, the availability of appropriate study and comparable control populations, resources available to conduct the study, and logistics.[3,4]

### Observational Studies

In observational studies, the exposure is not randomly distributed in a population. The investigator observes the exposure rather than selects the exposure status of an individual.[5] Types of observational studies include ecological, cross-sectional, case-control, and cohort.

Disease registries may be a data source for some cross-sectional surveys and cohort studies. A disease registry is typically formed when individual occurrences of a disease are obtained from multiple sources within a defined geographic area. The data from these sources are linked to avoid duplication of cases. Registries may be population-, hospital-, or clinic-based. Hospital- and clinic-based registries may identify potential participants for clinical research.[5,6] Examples of registries that collect longitudinal population-based data on rheumatic diseases include the National Data Bank for Rheumatic Diseases (http://www.arthritis-research.org/) and the Arthritis Internet Registry (https://www.arthritis-research.org/join-research/arthritis-internet-registry).

**TABLE 31-1** Common Epidemiologic Study Designs and Their Strengths and Weaknesses

| Study Design | Definition | Measure of Effect | Strengths | Weaknesses |
|---|---|---|---|---|
| Ecological | Aggregate data on exposures and disease; unit of analysis is a group, not an individual | Odds ratio | Inexpensive<br>Short duration<br>Hypothesis-generating | Susceptibility to confounding<br>Ecological fallacy |
| Cross-sectional survey | Data on exposures and disease obtained at one time from all individuals in an area (or a sample thereof) with and without disease | Prevalence<br>Odds ratio | Can study several outcomes<br>Short duration<br>Can generate population prevalence estimates of disease and risk factor distributions | May not be able to determine whether disease preceded exposure<br>Not practical for rare diseases<br>Cannot produce incidence or relative risk estimates |
| Case-control | Study of exposure/disease relationship in cases with a disease and controls without that disease, who are selected from source population from which the cases arose | Odds ratio | Best for studying rare conditions or those with long latency<br>Short duration<br>Small sample*<br>Inexpensive*<br>Odds Ratio can approximate Relative Risk | Inefficient for rare exposures<br>Potential bias from sampling cases and controls separately<br>May not be able to determine whether exposure preceded disease<br>Potential recall bias<br>Potential survivor bias<br>Cannot produce prevalence or incidence estimates |
| Cohort | Individuals without disease are followed during a period of time to determine which characteristics predict who will get the disease and who will not. | Incidence<br>Relative risk | Can determine sequence of events<br>Less susceptibility to survivor bias and bias in measuring predictors<br>Can study multiple outcomes<br>Can generate population incidence, relative risk | Frequently requires large samples<br>Not feasible for rare outcomes<br>More expensive<br>Long duration |
| Prospective | Study sample selected by investigator and followed forward in time for development of disease. | Incidence<br>Relative risk | Investigator control over selection of participants and measures | Increased expense<br>Long duration |
| Retrospective | Study sample and measurement of exposures and disease during a period of time have already occurred. | Incidence<br>Relative risk | Less expense<br>Short duration | Less control over selection of participants and measures |
| Nested case-control and case-cohort | Case-control study within the context of a prospective or retrospective cohort | Incidence<br>Relative risk | Underlying cohort design<br>Relatively inexpensive, compared to measurement on entire cohort | May require bank of samples that can be assayed at later date until or after outcomes occur |
| Randomized clinical trial | Exposure (pharmaceutical, non-pharmacologic device, educational intervention) manipulated by investigator | Relative risk<br>Hazard ratio | Most closely emulates an experiment<br>Strongest design to produce evidence for cause and effect<br>Random assignment of intervention minimizes confounding<br>May be faster and cheaper for some study questions than observational studies | Costly in time and money<br>Some research questions not suitable because of rare disease or ethical barriers<br>May not be generalizable if highly controlled environment does not reflect "real world" common practice<br>May have narrow scope and study question |
| Pragmatic clinical trial | Effectiveness of interventions evaluated in usual clinical practice conditions | Relative risk<br>Hazard ratio | Tests whether intervention works in real-life practice setting<br>Participants more likely to represent most individuals with the condition of interest<br>Results may be more generalizable to clinical care and more relevant to patients than efficacy trial | Participants and providers may be unblinded so important that assessors are blinded to group assignment |

*Relative to cohort study design.

## Ecological Studies

In this study design, the unit of observation is a group, rather than an individual.[6] Aggregate data on rates of disease and risk factors are compared to examine associations between disease frequencies and exposures. The ecological study is frequently a design of expediency, and can generate hypotheses for more rigorous testing in studies by using individual-level data.[4] One of its chief drawbacks is its high susceptibility to confounding. This occurs when an extraneous factor, not on the causal pathway, masks the true relationship between exposure and disease, by virtue of its association with both.[7] Further, associations in the aggregate may not necessarily hold true for the individual.[4] This concept is termed the *ecological fallacy*. As a hypothetical example, rates of specific kinds of cancers may be higher in countries in which cigarette sales are also high. Whether the individuals who are buying, and presumably smoking, the cigarettes are the same individuals in whom cancer develops is not known from this study design.

## Cross-Sectional Surveys

The goal of this study design is usually descriptive, including all individuals, with and without the disease under study, in the population, or a representative sample of them, at one point in time with no follow-up period. Surveys can estimate prevalence of a particular disease in the population and determine need for health services and resource allocation.[4] Typically, information about risk factors is obtained simultaneously. Such risk factor data may or may not represent the most relevant time of exposure, nor can it be determined whether the exposure preceded or resulted from the disease.[3]

An example of a cross-sectional survey, conducted approximately once per decade in the United States, is the National Health and Nutrition Examination Survey. This survey samples a proportion of the residents in the contiguous 48 states and measures various health outcomes and habits, such as blood pressure, serum lipids, height, weight, smoking, and dietary intake. These surveys have been used in rheumatology to determine the prevalence of radiographic knee and hip osteoarthritis (OA) in various age, sex, and race/ethnicity subgroups.[8]

## Case-Control Studies

Much maligned by the uninitiated because of its susceptibility to bias, the case-control study can be the study design of choice—or sometimes the *only* appropriate study design—in certain situations, particularly when the disease under study is rare. This type of study usually includes fewer individuals and is much less costly and more efficient than cohort studies. These advantages stem from the fact that it is composed of individuals who already have the disease under study, compared with the cohort study in which researchers must wait for the disease to develop in a small proportion of a large cohort with time. Most important in the design of a case-control study are (1) the choice of the control group, which must be comparable to the cases, and (2) recognition of potential biases that may threaten validity.

Strictly defined, the case-control study compares a group of individuals with the disease under study with a control population without the disease. Both groups are drawn from the same source population.[1,7] The source population may be the residents of a particular geographic area or a hospital's referral base. The control group serves as an estimate of the distribution of the exposure in the source population, and consequently, the control group must be sampled independently of exposure status.[1,7] For example, if researchers are interested in examining the possible association between smoking and progressive systemic sclerosis (PSS), the controls must be from the same source population that generated the cases of patients with PSS, if this can be determined, and must be sampled without regard to their smoking status.

### Selection of Controls for Case-Control Study

If the source of the cases is a well-defined population, the controls can be sampled directly from that population. If the source population is too large to allow a complete enumeration, controls may be matched to each case by their residence in the same neighborhood. Random-digit dialing can be used to select controls, but this labor-intensive method omits those without telephones or those who cannot be reached.[1] If the cases are drawn from a particular hospital or clinic, then the source population should represent people who would be treated in that hospital or clinic if they developed the disease under study, but frequently, this source population can be difficult to identify and is influenced by referral practices.[1] Hospital or clinic controls can be used, but this method can have particular pitfalls, because the controls might not be selected independently of the exposure in the source population. For instance, in a hospital-based study of smoking in SLE, individuals hospitalized for other diseases, such as myocardial infarction or pneumonia, might have exposures different from the source population in general, especially if the exposure, in this case smoking, causes or prevents the "control" disease selected. One way to avoid this is to exclude diseases known to be associated with the exposure under study, but this may create other biases. Another tactic could be to select hospital controls with diseases thought to be unrelated to the disease or exposures under study, such as traumatic leg fractures,[1] or to use several control groups selected by different methods.[4] For instance, sample controls might be chosen from hospitalized patients with diseases other than that under study, nonhospitalized patients in the same medical care system, or nonhospitalized individuals in the general population, comparing each control group separately with the diseased group.

### Weaknesses of the Case-Control Design

It is not possible to derive incidence or prevalence estimates from a case-control study. The greatest threat to validity is the inherent susceptibility to bias that can exist in this study design, because the cases and controls are sampled separately, and the assessment of exposure variables is retrospective.[4] Matching the cases and controls on factors such as age, sex, or race/ethnicity, can help ensure comparability of cases and controls to a degree. As mentioned above, more than one control group, selected in different ways, can be

used to see whether findings are consistent across control groups with different sampling biases. A nested case-control design (described later), in which a case-control study is performed within a larger cohort study, has the advantage of minimizing sampling bias because the cases and the controls would have been previously sampled in identical fashion into the parent cohort study.[4]

The other chief source of bias in the case-control study is recall bias, which occurs when exposures predating the disease are differentially reported by the controls and the cases, the latter of whom may have incentive to remember and report exposures. This can be partially prevented by using exposure data measured before the disease occurred, if available, and by blinding the observer and the participant to the exposure under investigation, or if possible, blinding them even to the specific disease under study and therefore, to case or control status. For example, in a case-control study examining racial/ethnic variation as the exposure variable of interest in SLE, race/ethnicity is immutable and thus not subject to recall bias. In contrast, if study participants know or suspect that prior exposure to hair dye, for instance, is the exposure of interest in the same case-control study, those with disease may be more prone to "remember" their exposure than those without disease. Investigators can obtain information about multiple potential exposures or even include several "dummy" exposures to mask the real hypothesis to try to minimize this type of bias.[9]

## Cohort Studies

Cohort studies follow groups of individuals without the disease in question during a period of time to describe the development or incidence of disease and to compare the incidence of disease between groups with different risk factors or exposures. Cohorts can be prospective or retrospective.[1,4]

### Prospective Cohort Study

Prospective cohorts are characterized by the selection of the cohort and measurement of risk factors or exposures before the outcome has occurred, thereby establishing time sequence or temporality, an important factor in determining causality. This design provides a distinct advantage versus the case-control study, in which exposure and disease are assessed simultaneously.

The primary disadvantage to the prospective cohort study is its expense. It requires large numbers of individuals to be followed up, potentially for long periods of time. Biases can creep in, particularly if there is significant loss to follow up. This study design is highly inefficient and inappropriate for study of rare diseases, but its efficiency increases while the frequency of the disease in the population increases.[4] For example, a prospective cohort study would be inappropriate to study PSS, because of its rarity, but excellent to study a common condition such as OA.[10,11]

### Retrospective Cohort Study

In a retrospective cohort study, individuals are followed during a period of time, but the cohort selection and collection of data have already occurred, sometimes for a different purpose than the current disease under study. For example, a cohort of individuals with small vessel vasculitis seen at a particular hospital between 1990 and 1992 could be identified, and data abstracted regarding baseline serologies, physical examination findings, and biopsy results when the patients were first evaluated. Then, examination of outcomes such as stroke or development of dialysis-dependent renal disease could be ascertained in 2000, by medical record review or by re-contact with the individuals so identified. Because exposure or risk factor assessment precedes assessment of outcome, this study design can establish temporality, as in a prospective cohort, and is less subject to recall bias that can hinder case-control studies. By selecting the cases and controls from the same source population, this study design also avoids some of the selection biases of case-control studies, in which the cases and controls are sampled separately. The retrospective cohort design is cheaper and more efficient than a prospective cohort, but because the data collection has already occurred, inferences from such a study are highly dependent upon the quality, completeness, and appropriateness of the original risk factor assessments to study their association with the disease in question.[4]

### Nested Case-Control and Case-Cohort Studies

These studies are case-noncase studies that occur within the context of a prospective or retrospective cohort, and are particularly useful to assess risk factor variables that would be too expensive to measure among all members of the cohort, such as biologic or genetic measurements.[4] In these designs, all members of a cohort who have experienced a particular outcome during the observation period (cases) are selected and compared with a subset of individuals within that same cohort. Full exposure or risk factor information is then collected. Sampling of these noncases differs between the nested case-control and case-cohort designs. In nested case-control studies, controls are sampled from individuals at risk for the outcome (i.e., they do not yet have the outcome but might have it in the future) at the same time that cases are identified. Controls may be selected to match cases on potential confounding variables (see Confounding), forming matched sets of cases and controls. In the nested case-control sample (i.e., cases and sampled controls for each case), exposure variables and covariates are then observed. In case-cohort studies, controls are derived from a subcohort sampled from the baseline cohort.[12] This subcohort is a random sample of the entire cohort, which means that selection of this subcohort is independent of whether or not an individual becomes a case; the subcohort may contain cases by chance. Data on exposures and covariates from the cases and subcohort sample are then collected and observed.

## Clinical Trials

### General Principles of Clinical Trial Design

The study designs described previously in this chapter are all observational designs that include no experimental manipulation of the exposure or outcome. Experimental

study designs or interventions include clinical trials, field trials, and community intervention trials.[6] Inferences from such trials of treatments assigned randomly to a large enough sample are much less likely to suffer from biases and other threats to validity than observational designs. In theory, randomization should eliminate most confounding, although some variation in risk factors between the intervention and control groups may occur by chance. This is more likely if the study size is small, and this possibility should always be ascertained and addressed in the analysis if necessary. The validity of conclusions from a RCT depends in part upon the avoidance of loss to follow up or participant dropout.

RCTs can be conducted for pharmacologic or nonpharmacologic interventions, such as dietary, physical activity, assistive devices, or educational interventions. Trials can include single or multiple dosages of the study intervention, placebo controls, active comparator controls in which the intervention of interest is compared to another agent whose efficacy is known, and combinations of interventions. For example, the Glucosamine/Chondroitin Arthritis Intervention Trial (GAIT) compared glucosamine hydrochloride alone, chondroitin sulfate alone, and the combination of glucosamine and chondroitin with placebo and with an active comparator, celecoxib, for their effects on symptoms of OA of the knee.[13-16] The Intensive Diet and Exercise for Arthritis (IDEA) trial was a nonpharmacologic rigorous weight loss intervention in which intensive dietary restriction, exercise, and the combination of diet and exercise were compared.[17] Such nonpharmacologic trials may include an "attention-control" in which the control group does not get the specific intervention of interest, but does get at least a minimal amount of attention from the investigator, because it is known that even minimal contact with the participants in a study can improve outcomes.[18] Optimally, to minimize bias, the study should be double-blind, in which the assignment of treatment is unknown to the participant and to the data collector evaluating the participant's response. A cross-over design is a within-patient design which allows each participant to be his/her own control and receive either the active intervention followed by a "washout" period in which no active or inactive treatment is given, and then the control treatment, or vice-versa. This design has some advantages, particularly in sample size requirements, but can be biased if there is a significant carry-over effect of the active treatment into the "control" observation period.[6] Response to treatment may also differ depending upon whether the active treatment is received before or after the placebo or other comparator.[19,20]

Other important considerations in RCTs are the selection and means of assessment of primary and secondary outcomes, which must be pre-specified. Outcomes can include measures of disease modification, symptom modification, and frequency of side-effects or other poor outcomes. Symptom modification trials are frequently of short duration and less expensive than disease modification trials, which generally are interested in longer-term outcomes. In RCTs of biologics for rheumatoid arthritis, for instance, effects on symptoms can frequently be measured in weeks to months, whereas effects on prevention or healing of radiographic erosions may require longer follow-up times.[21] Disease modification trials in OA that use radiographs generally require large numbers of individuals followed up for at least 2 years, predominantly because responsiveness to change in minimal joint space width is improved in studies of 2 years duration.[22,23] Outcomes based on magnetic resonance imaging exhibit moderate evidence for construct and predictive validity and good evidence for reliability and responsiveness, likely allowing for smaller sample sizes and shorter observation periods to demonstrate an effective response.[24] The Osteoarthritis Research Society International made recommendations to the Federal Drug Administration about study design, imaging modalities of choice, and other issues regarding structure modification in OA in 2011.[24]

Other trial designs can apply interventions to entire communities or to health care workers with measurement of outcome in their patients. An example of the latter would be the Patient and Provider Interventions for Managing Osteoarthritis in Primary Care (PRIMO) study,[25] in which patient-specific treatment recommendations for behavioral and clinical treatment of knee and hip OA (e.g., weight management, physical activity) are given to providers at the time of care. The physicians receive the intervention, but whether a particular intervention is prescribed and whether it improves patient symptoms, is measured by assessing the patient.

Although RCTs represent the "ultimate" study design closest to a controlled experiment, there are significant potential threats to its validity. Importantly, not all conditions can be subject to randomization. For example, in studying the association between cigarette smoking and rheumatoid arthritis, it would be unethical to randomly assign participants to smoking, thus only observational studies are possible. Another challenge of RCTs is that they generally are too short in duration to adequately assess therapeutic safety for many drugs and devices for which longer term outcomes are of public health interest. One of the most important biases can occur when there is large loss to follow up. To minimize this type of bias, every effort should be made to continue to obtain outcome information on all participants, even those who otherwise discontinue study assignment to therapy. Because all predictors of dropout cannot be known, and because dropouts may differ from individuals who remain in a study in ways that cannot be controlled, conventional analyses of treatment status are likely confounded.[6] Data may be analyzed in an intention-to-treat fashion, in which all randomly assigned participants are analyzed as a member of the group to which they were initially randomized, regardless of whether they actually adhered to the group assignment, but this analytical method can be biased by noncompliance leading to a misclassification of treatment status.[6] One method for dealing with treatment noncompliance suggested by Mark and Robins[26] includes making the assigned treatment a fixed covariate and received treatment a time-dependent exposure in a structural failure-time model. Completer, or "according to protocol," analyses are often also performed, in which only those who adhered to their assigned group treatment are included in the analysis. Per protocol analyses are generally not the primary analysis for efficacy in therapeutic trials, but they may be the most important analysis to examine for safety outcomes. Pre-randomization screening and run-in periods before randomization can help to avoid randomly

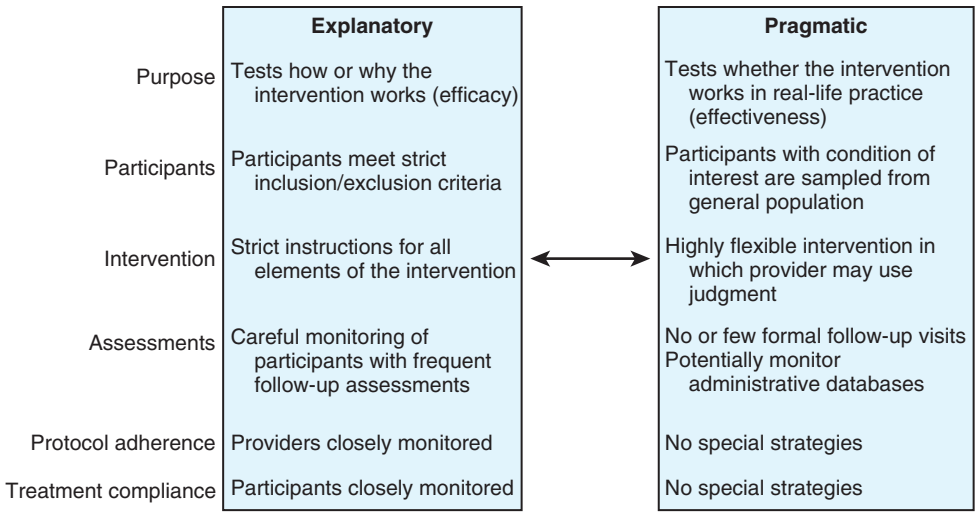

**Figure 31-2** Clinical trials: explanatory to pragmatic continuum.

assigning those unlikely to adhere to or complete the protocol, thereby minimizing expense and dilution of effects.[27,28] Other issues to consider in the interpretation of results of RCTs are generalizability and the difference between efficacy in a controlled environment and effectiveness in the real world of everyday practice (see section on Pragmatic Clinical Trials). Post-marketing observations can often reveal side-effects or unintended consequences of interventions that may not be apparent within the context of highly regulated trials.

## Noninferiority Trials

The most common type of RCT is the superiority trial, in which investigators determine whether a new treatment is more effective than placebo, no treatment, a lower dose of the test treatment, or an established treatment that is widely used or has known effectiveness. Noninferiority trials, on the other hand, are used to determine whether the effect of a new treatment is no worse than a reference treatment.[29-31] This differs from an equivalence trial, which aims to demonstrate that the effect of a new treatment is similar to the effect of the reference treatment.[29]

Designing and interpreting noninferiority trials can be challenging because of several weaknesses of this study compared with superiority trials. Intention-to-treat analysis (a commonly used approach in superiority trials, in which not all participants may have completed the treatment protocol) is not possible in noninferiority trials. Intention-to-treat tends to bias results towards the null (treatment equivalence), which, in a noninferiority trial, would result in an inferior treatment being incorrectly labeled as noninferior.[29,30] Additionally, an inferiority margin must be predetermined, and this margin may be subjectively based on the expectation of a minimally important effect or, more objectively, on the effect of the reference treatment in prior studies.[30,31] For the latter, the assumption is that the effect of the reference treatment in the noninferiority trial is similar to its effect in prior trials, which may not be true if the current and prior trials differ based on critical factors (i.e., study population).[29,30]

## Pragmatic Clinical Trials

Pragmatic trials evaluate the effectiveness of interventions in usual clinical practice conditions.[32] This study design differs from efficacy trials (Figure 31-2), which test interventions in ideal conditions among participants meeting strict inclusion and exclusion criteria. A continuum exists between pragmatic and efficacy trial designs,[33] and a purely pragmatic trial design is rare. Efficacy trials examine whether the intervention works among patients with specific demographic and clinical characteristics under certain conditions, whereas pragmatic trials examine whether the intervention works in real-life practice settings in a way that is relevant to the patients and generalizable in routine conditions. Thus, pragmatic trials offer higher external validity, whereas efficacy trials offer higher internal validity. Because exclusion criteria intentionally are less rigorous (e.g., only excluding individuals for whom there are significant safety concerns that preclude study participation), participants selected for pragmatic trials are likely to represent most individuals with the condition or disease of interest. For example, in the Benefits of Effective Exercise for Knee Pain (BEEP) study,[34] the investigators purposely chose to not use radiographic diagnosis of knee OA as a criterion for study inclusion because they wanted study participants to represent patients typically seen in primary care.

## Cluster Randomized Implementation Trials

A cluster-randomized implementation trial does not randomly assign at the individual-level, but rather by group (e.g., clinical practices or hospital sites). This type of trial design is especially useful in comparative effectiveness and implementation studies, particularly if the intervention is implemented at the cluster level,[35] such as among teams of healthcare providers. Also, the cluster-randomized design may help prevent treatment group contamination by separating groups by location or time.[35] However, contamination can occur in cluster-randomized trials if there is spillover of the exposure to treatment and control conditions between the clusters. For example, an educational

intervention might be administered at the patient level that aims to "activate" patients in an effort to influence the patient physician communication about effective osteoporosis treatment prescribing. Because prescribing occurs by doctors, random assignment is performed at the doctor level and patients are nested within clusters of doctors. If a doctor is randomly assigned to the control cluster, but some of her patients are inadvertently exposed to the educational intervention, this contamination could affect her management of her other patients in the control arm of the study and adversely impact the internal validity of the study findings. To reduce the risk of recruitment bias, participants or recruiters of participants should be blinded to cluster assignment at time of enrollment,[36] or random assignment of clusters can occur after enrollment of groups. Standard approaches to calculating sample size would provide an underestimate. To account for the lack of independence among individuals within the same cluster, the average cluster size and degree of correlation within clusters must be considered and the "design effect" (inflation factor) should be included in sample size calculations.[32] Power is influenced by the number of clusters rather than the size of the cluster.[37] Furthermore, analytic approaches should account for the unit of analysis (the cluster),[37] such as mixed linear models, hierarchical linear modeling, and generalized estimating equations.

## Comparative Effectiveness Research and Patient-Centered Outcomes Research

Evidence of effectiveness of treatments is necessary for informing medical decisions by clinicians, patients, and caregivers, reducing healthcare costs, and improving outcomes. Comparative effectiveness research (CER) generates evidence on the effectiveness of treatments with the goal of determining which treatment is best for particular groups of people with certain conditions to improve the quality of treatments and outcomes.[38] Systematic reviews may be conducted in which all results from existing studies are compiled and the benefits and risks of the treatments are evaluated across different populations. Alternatively, new studies may be conducted to examine the effectiveness of a treatment, including its benefits, its side effects, and costs compared to other available treatments for a given outcome in a specified population.

The quality of health care has continued to improve during the past decade in the United States, yet the increasing costs and financial burden of health care, as well as regional differences in treatment use, cost, and outcomes, are concerning.[38,39] For example, Fisher et al.[40] report that individuals in the highest-spending regions received 60% more healthcare than the lowest-spending regions, but this additional care did not result in improved mortality rates, functional status, or patient satisfaction. The rising healthcare costs and distressing regional differences have given rise to a push for focused efforts on CER nationally. Under the American Recovery and Reinvestment Act (ARRA) of 2009, Congress allocated $1.1 billion to spark the advancement of CER nationally to improve healthcare quality while reducing costs.[38] As required by the ARRA, the Institute of Medicine (IOM) Committee on Comparative Effectiveness Research Prioritization selected 100 health topics requiring CER, including osteoarthritis (musculoskeletal disorders) and rheumatoid and psoriatic arthritis (immune system, connective tissue, and joint disorders), based on the input of public and private stakeholders.[38] For additional information on the national priorities of CER, the IOM's Initial National Priorities on Comparative Effectiveness Research is available at the National Academies Press website (www.nap.edu).

### Patient-Reported Outcomes

Central to Patient-Centered Outcomes Research (PCOR) is measuring the outcomes that matter most to patients. International efforts, supported and endorsed by organizations such as United Kingdom's National Institute for Health and Care Excellence (NICE) and German Institute for Quality and Efficiency in Health Care (IQWiG),[41] are advancing the promotion of patient engagement to define and improve quality of care criteria for specific conditions, and great strides have occurred in rheumatology around patient-reported outcomes (PROs). These are discussed in Chapter 33, and both older PROs such as the Health Assessment Questionnaire (HAQ) and somewhat newer ones such as Routine Assessment of Patient Index Data (RAPID 3) are critical to the study of many of our disease states. The PRO field is moving toward computer adaptive testing (CAT) using item response theory (IRT).[42] The principle of this newer form of PROs is to use the response of an initial question to guide the next PRO question. For example, a patient who can run a mile is not asked about their ability to do activities of daily living, but is next given survey items selected based on their performance level noted. Population normative data are growing for these approaches, and one initiative that uses the Patient-Reported Outcomes Information System (PROMIS)[43] has gained international recognition as a newer state-of-the-art PRO measure.

# BIASES IN STUDY DESIGN

Error in a study may be random (chance) or systematic (bias). Bias includes errors in the selection of participants, errors in measurement of a variable, or confounding. Bias may produce an incorrect conclusion about the association between an exposure and disease.

## Selection Bias

The procedures used to select participants for a study or factors related to study participation may result in a different exposure-disease association between participants and nonparticipants. Selection bias may occur in any study design, most notably in retrospective or case-control studies where the exposure and outcome both occur before selection of participants. Differential participation may arise in cohort studies or clinical trials with loss to follow up, particularly if participants leave the study for reasons related to the exposure or the disease.

## Information and Recall Bias

Errors in the measurement or collection of information may occur. If a variable is measured categorically, information

about a participant may be placed in the wrong category, or misclassified. Nondifferential misclassification of an exposure occurs when misclassification is not related to the presence of disease.[1] Misclassification is differential if exposure differs by disease status.[1] Similarly, misclassification of a disease is nondifferential if it does not differ by exposure status and differential if it varies by exposure status. Nondifferential misclassification biases an association between exposure and disease towards the null, except if the association is the null. Differential misclassification may bias the association in either direction.

In case-control studies, those who are cases may have a different recall of their exposure history than those who are noncases. This difference in recall can introduce a bias that inflates the estimate of an association between exposure and disease. Recall bias is differential misclassification because the exposure is misclassified differently among cases and controls.[1] Methods for reducing recall bias include structuring questions to improve recall for both groups, selecting a control group that would be more likely to have good recall of exposure history, or use of information other than interviews, such as medical records.[1]

## Confounding

Confounding occurs when there is a "mixing of effects" between the exposure, outcome, and a third factor.[44] Specifically, a confounding variable is a risk factor for the disease, is associated with the main exposure, and is not an intermediate step on the casual pathway from exposure to disease.[6] For example, when examining leg length inequality as a risk factor for lower extremity OA in a cohort study, a likely confounding variable would be injury to the lower limb. Injury is a risk factor for OA, it is associated with leg length inequality (a severe injury to a lower limb can result in a shortening of that limb), and it precedes both OA and leg length inequality. Methods used to control confounding include stratifying data by the confounding variable or including the variable as a covariate in multivariable statistical models. Matching may reduce confounding in case-control studies. In experimental studies, random assignment is a strategy to reduce confounding.

The amount of confounding is an important consideration in determining whether one should control for it in analyses.[6] If the estimate of an association minimally changes after adjusting for a potential confounding variable (e.g., unadjusted odds ratio [OR] = 2.62, adjusted OR = 2.58), the inclusion of the variable as a covariate in a multivariable model may not be necessary. However, if the estimate changes profoundly (e.g., unadjusted OR = 2.62, adjusted OR = 1.05), then methods to control confounding should be used to reduce bias in the association.

### Confounding by Indication and Channeling in Observational Studies of Therapeutics

In observational studies of therapeutics, delivery of treatment is not randomized, and the reason for treatment may be based on health risks.[45,46] Because the risk profiles between treated and comparison groups differ, results may be biased. Channeling occurs in observational studies when drugs are prescribed ("channeled") to patients differently based on prognostic characteristics or disease severity.[47] Channeling can make study outcomes related to a drug appear better or worse than they truly are, incorrectly attributing health benefits or adverse events to the drug. Confounding by indication is a type of channeling bias that occurs when the indication for which a drug is prescribed (drug exposure) is an independent risk factor for the outcome.[45,46] There has been considerable controversy in rheumatoid arthritis, for example, about the role of low-dose glucocorticoids and their association with adverse outcomes such as infections and cardiovascular disease. It is clear that considerable confounding is present by indication around glucocorticoid use, whereby patients with more active/severe RA are more likely to be prescribed glucocorticoids, and these same patients, in turn, are also the group most likely to experience an adverse outcome that may or may not be fully attributable to the low-dose glucocorticoid, but instead to their underlying disease state.[48]

### Analytic Methods to Address Confounding by Indication

Methods available for accounting for confounding by indication in observational studies include propensity scores, instrumental variables, and marginal structural models. The propensity score is the probability that a participant received a treatment.[49] In a randomized controlled study, the propensity score for each participant would be 0.5 if assignment was determined by a coin toss. In observational studies, the propensity score is unknown and is estimated based on baseline participant characteristics. The propensity score can be used analytically in different ways to assist with balancing the study groups to make them analogous. By considering the propensity score when comparing groups, the observational study becomes similar to a randomized block study in which each block represents a group of participants with the same propensities. The use of instrumental variable is another approach to control for confounding by indication. The overall goal is to select a factor, or instrument, that is strongly associated with the treatment but has no association with the potential outcome or possible confounders (co-variates). Including this factor in statistical models in many ways mirrors a RCT. An example in rheumatology is an observational study of the association of cyclo-oxygenase (COX)-2 selective NSAIDs (also known as coxibs) with gastrointestinal (GI) bleeding.[50] In this study, the last NSAID prescription written by a given physician (to either a traditional nonselective vs. a coxib) was used as an instrument to adjust for confounding by indication associated with the preferential choice of coxibs for patients at higher risk of GI bleeding. Last, an even newer method involving marginal structural models with inverse probability weighting affords a sophisticated analytic approach to partially address this same issue.[51]

## EFFECT MEASURE MODIFICATION

Two factors are considered to be independent if the combination of their effects is equal to their joint effects. If the effect of one factor depends on the effect of another, effect measure modification exists. This concept is also known as *statistical interaction*. Examining effect measure modification

allows researchers to investigate whether the association between exposure and disease differs across subgroups. For example, Krishnan and colleagues.[52] reported a strong association between past history of smoking and RA in men (OR, 2.0; 95% CI, 1.2-3.2), but not women (OR, 0.9; 95% CI, 0.6-1.3). Upon further exploration, this association was only seen among men with rheumatoid factor-positive RA. If effect measure modification is not considered, results could be biased or important groups for targeting interventions could be missed.

## SCREENING

Screening is an important public health strategy in reducing morbidity and mortality.[44] Screening tests classify a person who is asymptomatic as likely or unlikely to have the disease. This differs from diagnostic tests, which determine whether a person with signs or symptoms of a disease truly has the disease. If a screening test suggests a high likelihood of disease, then further diagnostic evaluation may occur to confirm disease presence. Although not applicable in all diseases, the early detection of disease when a person is asymptomatic is felt to result in more effective treatment than if disease detection occurs later when symptoms develop with advanced disease.[44] To determine the validity of a screening or diagnostic test, one must establish the sensitivity or specificity of the test. Often, a new test may be compared with a "gold standard" of the definition of a disease, although this standard may not encompass all signs and symptoms of that disease. For example, biologic markers may be useful screening tools for detecting early changes in joint health that lead to OA. The presence of radiographic features of OA may be used as a comparative "gold standard," yet this definition of OA lacks other components used to diagnose the disease, such as pain, aching, or stiffness in the joint.

### Sensitivity

*Sensitivity* is the probability that a test will correctly classify a case. This is expressed as a proportion of the number of cases identified by the test out of the total number of individuals with the disease. In screening, sensitivity is the probability of correctly classifying an individual as a detectable, pre-clinical case. If a test correctly provides a positive test result for 37 out of 43 people with disease, the sensitivity of the test is 86% (Table 31-2).

### Specificity

*Specificity* is the probability that a test will correctly classify a noncase. This is expressed as a proportion of the number of individuals without disease identified by the test out of the total number of individuals without disease. If a test correctly provides a negative test result for 62 out of 66 people without disease, the specificity of the test is 94% (see Table 31-2).

**TABLE 31-2** Hypothetical Distribution of Patients by Disease and Test Result.

| | Disease | No Disease | Total |
|---|---|---|---|
| Positive Test | 37 | 4 | 41 |
| Negative Test | 6 | 62 | 68 |
| Total | 43 | 66 | |

### Predictive Value

Predictive values are used to interpret the results of a test by examining the correct classification of individuals by the test. This measure is valuable because whether a person is truly a case or noncase is difficult to know (for determining sensitivity or specificity), but a positive or negative result of a test is known. A positive predictive value is a proportion of the number of cases identified out of all positive test results. If 37 people truly have disease out of 41 with a positive test result, the positive predictive value is 90% (see Table 31-2). A negative predictive value is a proportion of the noncases identified out of all negative test results. If 62 people truly do not have disease out of 68 with a negative test result, the negative predictive value is 94% (see Table 31-2).

## CONCLUSION

Epidemiologic methods can be used to measure frequency or development of disease and evaluate risk or protective factors in disease occurrence. Choice of study design depends on multiple factors, including the research question, disease under study, availability of appropriate study populations, and resources available. Each study design has its own set of advantages and disadvantages, with the clinical trial considered the most rigorous.

CHAPTER 32

# Economic Burden of Rheumatic Diseases

Edward Yelin

**KEY POINTS**

- Studies of the economic burden of diseases help allocate health care resources for musculoskeletal conditions in which mortality rates are less prominent.
- The economic burden is determined by summing expenditures for medical care, called "direct costs," and earnings losses and value of productivity losses in other activities, called "indirect costs." Per person direct costs of musculoskeletal conditions have risen by more than 61% in the United States during the past two decades, to $7768 in 2011 dollars.
- Much of this increase is fueled by a 60% increase in the United States in the number of prescription medications used each year by people with musculoskeletal conditions and by a 68% increase in the price per prescription.
- Per person earnings losses among individuals with musculoskeletal conditions have risen by almost 105% during the same time, to $1224 in 2011 dollars.
- Insured people with musculoskeletal conditions experienced dramatically higher medical care costs than people without insurance, suggesting that before health legislation in the United States, those without insurance did not receive the care they needed.
- The aggregate economic impact of musculoskeletal conditions in the United States has increased by approximately 120% during the past two decades, from the equivalent of 3.4% to 7.6% of the gross domestic product.
- The increasing use of biologic agents for rheumatoid arthritis has led to a rapid increase in the direct costs associated with this condition. The costs of these agents alone exceed the total costs of rheumatoid arthritis from the prebiologics era, including direct and indirect costs.

Cost-of-illness studies are used to provide a measure of the impact of medical conditions, and can overcome the natural tendency of policymakers to focus attention on those conditions with high mortality rates, to the exclusion of those with a high impact on quality of life.

Studies of the economic impact of musculoskeletal conditions as a whole in the United States have been conducted since the early 1960s by using a mélange of publicly available data sources. Such studies indicate that during three decades, the economic impact of musculoskeletal conditions increased from the equivalent of approximately half a percent of the U.S. gross domestic product (GDP) to more than 2.5%. During the past two decades, the availability of a well-designed individual data source in the United States, the Medical Expenditures Panel Survey, has permitted researchers to estimate the economic impact with greater precision and to show that during this time frame, the economic impact increased by the equivalent of approximately 4 percentage points of GDP, to slightly less than 8%. In the Great Recession that began in 2008, GDP declined by approximately 7%, so the economic impact of musculoskeletal conditions can be said to approximate the impact of the Great Recession, although the effect is chronic, not acute.

A substantial literature now exists on the economic impact of rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and osteoarthritis (OA). The studies in this literature are largely based on clinical samples, most from tertiary care centers, and indicate that there are substantial costs associated with all three conditions. This was true for RA even before the development of biologic agents. The most recent studies of RA indicate that, with the advent of these agents, the costs of RA have skyrocketed, with costs from biologic agents alone eclipsing the total costs of RA before their development, including all other medical care costs and all wage losses.

The economic burden of musculoskeletal conditions is rapidly increasing in developing nations. Each discipline may use different tools to assess the burden of disease. Rheumatology health professionals may measure the impact of these conditions by estimating both the discomfort and disability they cause and to what extent professionals may alleviate these factors by providing health care. Psychologists may measure the impact of musculoskeletal conditions on the achievement of mental equipoise, or its opposite, mental discomfort. Economists take the measurements provided by other disciplines and turn them into monetary equivalents to describe the magnitude of the burden associated with musculoskeletal conditions. Thus economists are concerned with the monetary value of the resources used to produce health and with the return on the use of those resources in terms of reduced impacts of illness on pain and functioning. Cost of illness is an accounting of the resources spent in pursuit of health and of the residual amount of discomfort and disability left after those resources are spent[1-4] (Table 32-1).

Economics is far more than a positive science, that is, a discipline that observes how things are rather than seeking to change them. The normative part of the discipline has dual and sometimes competing goals.[5,6] The first of these is to ensure that resources are allocated equitably (i.e., making sure that they are distributed fairly across individuals). The second is to make sure that they are used efficiently (i.e., as well as contemporary technology permits to produce goods).[7]

**TABLE 32-1** Principal Methods to Assess Costs of Illness

There are two principal methods to assess the costs of illness.

1. The human capital approach, developed by Dorothy Rice when she was at the Social Security Administration and, later, the National Center for Health Statistics,[1,4] and
2. The willingness-to-pay approach.[5]

The two methods do not differ in the way that they assess the direct costs of medical care. For the indirect costs associated with loss of function and the intangible impacts of disease, the human capital approach uses the market value of the labor to reduce the impacts (e.g., by hiring a replacement worker).

In a variant of the human capital approach called the friction method,[3] the losses are estimated from the perspective of the employer and only last until the replacement worker is hired and then achieves the same productivity as the worker who left as a result of disease.

At that point, an employer would be said to incur no additional costs from the onset of the prior incumbent's disease. The willingness-to-pay approach values the loss of function as the amount the affected individual would pay to restore the function, which may be more, the same, or less than the amount it would take to replace the worker in the labor market.

The human capital approach is more reliable in estimating the economic impact of the lost productivity of affected individuals because the cost of labor is well established in all advanced societies and, therefore, easy to estimate.

The human capital approach, however, only enumerates the intangible impacts of disease (e.g., the burden associated with the experience of intense pain) but does not translate them into economic terms. The willingness-to-pay approach can theoretically incorporate all of the costs of disease in those terms, although as a practical matter there are problems associated with attempting to do so.[6]

In health, resources would be distributed equitably if people with similar levels of health received relatively equal access to health care services that reduce the burden of disease and which, based on a thorough knowledge of the treatment options, they chose for themselves. Similarly, in health, resources would be used efficiently if they produced the health outcomes people wanted while leaving the maximum amount to be used for other purposes, what economists refer to as "the opportunity cost" of those resources.

The pursuit of equity and efficiency may work in harmony. If resources are used efficiently to provide health care, then more can be allocated to ensure that everyone has access to the same set of services they desire. But the opposite is also true: if resources are used inefficiently, then the "wastage" cannot be redistributed to ensure that everyone has equal access.

The evidence that the distribution of health care resources in the United States is inefficient has been increasing for several decades and stems from studies conducted within the United States[8,9,10] and from those that compare the United States with other nations.[11-13] The inequitable distribution, however, has also recently become a central focus of analysis and policy. The signposts for inefficiency might be said to include the use of any test or procedure for which evidence has emerged suggesting that the test or procedure does not work or does not work as well as alternatives that are available. Every comparative trial that does not result in a decreased use of the comparator that worked less well is, thus, evidence in support of the argument that our system of care is inefficient. However, the most compelling evidence comes from studies that compare populations of regions for the use of select tests and procedures and fail to find that those areas that use more of one achieve better health outcomes.[14] Similarly, international comparisons often show that the extra usage within the United States fails to improve health-related quality of life, let alone longevity in comparison with other nations.[11] Such studies also fail to show that the extra usage engenders greater satisfaction with most aspects of care.

The methods and data sources to estimate the economic burdens of disease, the positive side of health economics, have certainly improved during the years since the first cost-of-illness studies for the nation as a whole were completed by Dorothy Rice and colleagues. Subsequent to the development of the methods of cost-of-illness studies by Rice and others, individual investigators used those methods and the availability of clinical samples to provide highly specific estimates of discrete rheumatic conditions, particularly RA.[15] For national estimates, the U.S. federal government has developed an annual survey, the Medical Expenditures Panel Survey (MEPS) to provide reliable estimates of the cost of illness experienced by individuals.[16-18] The prior work by Rice relied on separate data sources about ambulatory care, hospital admissions, and nursing homes. The same individuals were not included in each of these data sources; indeed, the data sources were based on samples of medical care encounters rather than of individuals with specific conditions. MEPS provides estimates on every kind of health care for the same individuals and does so through systematic sampling of the U.S. population. Because of the uniformity of data collected in each year, it provides the opportunity to merge multiple years of data so that sample sizes are sufficient to provide estimates of the cost of fairly rare conditions reliably.[19] Similarly, the batteries of items to measure impact in each domain (e.g., the magnitude of the ambulatory care used) have been vetted through reliability studies comparing survey responses with medical records and billing information. The one aspect of cost-of-illness studies that cannot be replicated by using MEPS concerns the indirect costs associated with mortality. Thus a full accounting of the costs of illness would include an estimate of the discounted present value of lost earnings among those who die prematurely. Although mortality rates are elevated for those with inflammatory rheumatic conditions,[20-23] in general, musculoskeletal conditions are not associated with dramatically higher mortality rates. Therefore the bias in estimates of the costs of these conditions by using MEPS data is relatively small.

The comprehensive sampling and reliability of batteries notwithstanding, the findings from the studies of Rice and colleagues about all kinds of conditions in the nation as a whole and the studies about people with discrete conditions in clinical samples stand the test of time. Thus the early and contemporary studies both highlight the effect of population dynamics, particularly the aging of the population; increase in the cost of care as a function of changes in the kinds of services provided and increase in the unit price of those services; and changing employment circumstances and attendant wage losses on the burden of disease experienced by individuals with musculoskeletal conditions.[19]

The tools of the normative part of economics have also evolved with time (Table 32-2). The tools are normative

**TABLE 32-2** Economic Methods to Assess the Value of Health Interventions

| |
|---|
| Concise reviews are available of the methods to estimate the relationship between health care expenditures and the returns of these expenditures in terms of health-related quality of life including one of its domains, employment. |
| When alternative levels of health expenditures will result in improved outcomes, attempts are needed to reduce the wastage of health expenditures, the subject of "cost-minimization studies." |
| When alternative treatments for a condition are available, "cost-effectiveness analysis," which shows the relative returns from these alternatives in a common natural metric (e.g., longevity), is used. |
| When comparing alternative investments across conditions, an outcome metric that applies to all conditions equally is needed; often the easiest outcome to measure in common terms is the dollar value of lost wages, the subject of "cost-benefit analysis." However, there are inherent problems in translating outcomes into dollar terms. |
| Economists have developed common metrics as the quality-adjusted life year, which takes into account the value individuals in society place on achieving a common outcome (economists use the term *utility* for these evaluations and use the term *cost-utility analysis* for assessing the returns on alternative health expenditures). |

because they are based on the notion that certain levels of health care expenditures unnecessarily divert resources from other uses, and that society should have allocative mechanisms, through the market or regulatory means that redirect resources away from specific conditions or, more frequently, specific treatments for those conditions. That direct medical care expenditures for RA equal "x billion dollars" is a positive statement; that society should not be spending "y billion dollars" on specific treatments for RA is a normative statement; that a treatment achieves an end (e.g., extending life or reducing disability-adjusted life years, or DALYs) less expensively than another, the product of a cost-effectiveness analysis, is a tool that may provide a guide in reallocating resources from RA care, in putting in place a policy to implement the notion that spending "y billion" on specific treatments for RA is not a good use of those resources.

This chapter summarizes the evidence accumulated on the current burden of musculoskeletal conditions overall, as well as on specific conditions within that overarching rubric. This is similar to indicating the temperature outside but not indicating whether that temperature is hot or cold. Thus it is impossible to determine whether the tools to assist in redirecting resources such as cost-effectiveness analysis should be used. However, although the evidence base that supports individual treatments for musculoskeletal conditions, for example, use of one or more disease-modifying agents in RA, or entire strategies of treatment, for example, the use of both pharmaceutical and behavioral interventions for OA increases, we begin to be able to move from the positive aspects of health economics to the normative.

## STUDIES OF THE COSTS OF ALL FORMS OF MUSCULOSKELETAL DISEASE

In this section, data from the United States and elsewhere about the economic impact of musculoskeletal conditions as an entire category are presented.* Three-year averages smooth out individual discrepant values in any one year caused by small sample sizes. The first triad of years, thus, incorporates data from 1996 through 1998, whereas the last incorporates data from 2009 through 2011. All data represent annualized figures. Between 1996 to 1998 and 2009 to 2011, little change has occurred in the use of physician visits or hospital care for people with musculoskeletal conditions. In each triad of years, approximately 85% of such people have one or more physician visits, and the average number of visits per person has not changed, averaging approximately 5.6 a year in the initial and last 3-year periods. Similarly, the proportion with one or more hospitalizations has remained relatively constant in the range of 11% to 12% a year, with the average number of admissions holding steady at 0.2 per person per year. In contrast to physician visits and hospital care, there has been substantial growth in the use of other ambulatory care (for example, physical therapists, occupational therapists, nurses and nurse practitioners, physician assistants, and chiropractors) and prescription medications. Between 1996 to 1998 and 2009 to 2011, the proportion with any use of ambulatory care other than physicians increased by 30% in relative terms, from slightly less than 40% to approximately 52%, and the number of visits per year to such providers increased by 42%, from 2.6 to 3.7 per year. The growth in the use of prescription medications was substantial. Although the proportion with one or more prescription inched up from approximately 81% to 84%, the average number of medications per person increased by approximately 60%, from 13.1 to 20.8.

The unit price of ambulatory visits, including both physician visits and those to nonphysician providers, increased from $186 in 1996 to 1998 to $281 in 2009 to 2011, or by approximately 51% in real terms. The unit price of hospital admissions also substantially increased, from $8792 in 1996 to 1998 to $11,184 in 2009 to 2011, or by more than a quarter in relative terms. The unit price associated with prescription medicines increased the most, 68%, from $51 in the 1996 to 1998 period to $85 in 2009 to 2011. The third set of columns, per-person costs, shows the product of the average number of units of services used and the unit prices. Total per-person costs increased by approximately 60% between 1996 and998 and 2009 to 2011, from $4832 to $7768. The overall increase was driven overwhelmingly by increases in prescription drug costs, but with smaller contributions from ambulatory visits and hospital admissions. Prescription drug costs increased by 167% between 1996 to 1998 and 2009 to 2011 in constant dollars, from $665 to $1778. Ambulatory visit costs increased by slightly more than 70% during this time frame, from $1522 to $2614, hospital costs increased by approximately a quarter, from $1758 per person in 1996 to 1998 to $2237 in 2009 to 2011. As a result of the growth in the costs of prescription drugs, the proportion of all medical care costs attributable to drugs increased from 14% to 23% of the total, whereas the total attributable to ambulatory care increased only

*The results are based on the author's analysis of MEPS data. The methods were described in a 2001 publication[24] and replicated in subsequent publications.[25,26]

slightly to 34%, and the shares attributable to hospital admissions and the residual category actually decreased. Another way to assess the cost of illness is to estimate the increment in total costs beyond those that would be incurred on behalf of people similar to those with musculoskeletal conditions but who do not actually have such conditions. There are two ways to make these estimates: by asking individuals to apportion health care episodes to various causes and by using regression techniques that take into account the health and demographic characteristics of the individuals, because the attributions made by the individuals may not be reliable. With use of the second method, approximately 30% of the costs incurred by individuals with musculoskeletal conditions can be attributed to those conditions.

The aggregate medical care costs associated with musculoskeletal conditions are the product of the costs per case and the number of persons with the conditions at any one time. The aging of the population is resulting in a substantial increase in the number of persons and percentage of the population with musculoskeletal conditions in the United States. Between 1996 to 1998 and 2009 to 2011, the number reporting one or more musculoskeletal conditions increased from 76 to 102.5 million, or by more than a third in relative terms, whereas the percentage of the population with such conditions rose by approximately a fifth in relative terms, from 28% to 33.2%. When multiplied by the cost per person in each triad of years covered by the analysis, the aggregate costs rose from $367.1 to $796.3 billion in constant dollars, or by 117% in relative terms. The dual importance of population aging and increases in the cost per case in the dynamics in the aggregate costs of musculoskeletal conditions can be seen by the fact that the increase in the former, more than a third, and the percentage increase in the latter, 61%, were both substantial.

The relatively large increase in the cost per case of all musculoskeletal conditions would have been even greater were it not for the fact that the vast majority of cases within the overall musculoskeletal diseases rubric are OA and similar mechanical diseases rather than such autoimmune conditions as RA or SLE. Treatments for OA, for example, have been relatively stable over time. As explained later, costs for individual autoimmune conditions have risen substantially over the past decade as new treatments such as the biologics for RA have taken hold.

Musculoskeletal conditions are more prevalent among females; females with the conditions also experience per-person medical care costs that are slightly higher than males, $8075 compared with $7865. When the higher prevalence and higher per-person costs are combined, aggregate costs are $464.6 billion among females and only $362.5 billion among males. Per-person medical care costs associated with musculoskeletal conditions increase monotonically with age, from a low of $3288 among those younger than age 18 to a high of $11,708 among individuals 65 or older. However, because of the number of persons in the 45- to 64-year-old group, aggregate costs are actually slightly higher in the latter group than among those 65 or older, $348.9 billion versus $305.4 billion. Nonwhites and whites with musculoskeletal conditions experience similar per-person costs, $7949 and $8154, respectively. On the other hand, Hispanics with musculoskeletal conditions incurred medical care costs of $6305 versus $8180 among non-Hispanics, about a quarter lower in relative terms. Per-person costs did not differ systematically by education level. Probably reflecting age and severity, costs were greater among divorced, widowed, or separated individuals ($8849) than among those who were married or living with a partner ($7970) and especially than among those who have never been married ($6612). Of note, people with musculoskeletal conditions reporting public insurance actually incurred higher medical care costs than those with private insurance ($10,142 vs. $7842, a difference of about a quarter), but both groups had substantially higher costs than those without insurance, who averaged only $2479 per person in medical care costs, a difference of more than two-thirds relative to those with any private insurance and 75% relative to those with any form of public insurance. Thus it cannot be said that those without insurance necessarily receive the care they need. The years analyzed, 2009 to 2011, predate full implementation of the recent health care legislation in the United States.

Earnings losses associated with musculoskeletal disorders among the working age population, the component of indirect costs calculable in MEPS, are substantial and growing in real terms. The number of individuals with a work history between ages 18 and 64 increased from 48.5 million in the first triad of years covered to 63.4 million in the last triad, or by about a third. Concurrently, the per-person earnings losses among working age people with musculoskeletal conditions increased from $596 to $1224, or by more than 100% in real terms (although it has declined somewhat in the most recent three-year periods). As a result of the increase in the prevalence of the at-risk population and the per-person earnings losses among such people, aggregate earnings losses among people with musculoskeletal conditions rose from $28.9 billion in 1996-1998 to $128.6 in 2003-2005; it has since decreased to $77.5 billion. The decreased per-person and aggregate earnings losses may reflect relative stasis in wages in the United States, a phenomenon which may affect the population at risk for work loss, that is, those who are unable to continue working with the onset of physical impairments due to musculoskeletal conditions.

Figure 32-1 summarizes the overall economic impact of musculoskeletal conditions since the initiation of the MEPS in 1996. During the less than two decades since the MEPS began, the total costs of musculoskeletal conditions have risen from the equivalent of 3.4% of GDP to 7.6%. The bulk of the costs—and the bulk of the increase—are the result of increases in the medical care costs. Medical care costs among individuals of all ages with musculoskeletal conditions have risen from the equivalent of 3.2% of GDP to 6.9%, or by about 117% in relative terms, while the earnings losses, estimated here only for those aged 18 through 64, have increased from the equivalent of 0.3% to 0.7% after the recent decrease.

A recession is said to occur when the economy contracts by 1% of GDP or more for two quarters or more. In the deep recession that began in 2007, GDP fell by about 7%[27]; on an annualized basis. The economic impact of musculoskeletal diseases can therefore be said to be the equivalent of a severe recession, although to judge by the increases over time, the onset occurs more slowly. However, the

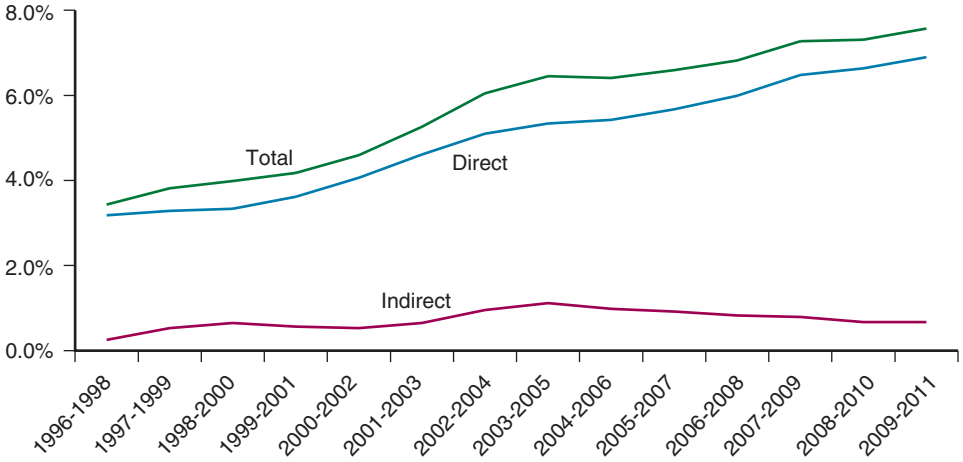

**Figure 32-1** Direct, indirect, and total costs of musculoskeletal conditions as a percentage of gross domestic product, United States, select years. *(Data [pre-1995] from Rice D, Hodgson T, Kopstein A: The economic costs of illness: a replication and update.* Health Care Fin Rev *7:61-80, 1985; Badley E: The economic burden of musculoskeletal disorders in Canada is similar to that for cancer, and may be higher.* J Rheumatol *22:204-206, 1995; Odonnell S LC, McRae L, Bancej C: Life with arthritis in Canada: a personal and public health challenge.* Chronic Dis Inj Can *31:135-136, 2011; Arthritis Foundation of Australia: Cost of arthritis to the Australian community.* Industry Commission Report *14-22, 1994; and Arthritis and Osteoporosis Victoria:* A problem worth solving, *2013. impact is permanent, at least until medical care expenditures either result in improved functionality and concomitant reduced earnings losses or, without that impact, are reduced by decreases in the amount of health care used and/or the unit prices of the services used to treat this group of conditions.

## OTHER NATIONS

Studies on the economic impact of musculoskeletal conditions have been conducted in Canada,[28,29] Australia,[30,31] the United Kingdom,[32] Sweden,[33] and the Netherlands.[34,35] Systematic reviews, incorporating both methodological considerations[36] and comprehensive review of evidence across countries, have also been published.[37] All use methods broadly similar to the studies in the United States conducted by Rice and colleagues.[38] The most recent Canadian study[29] using 2000 data but published in 2011, showed that the economic impact of musculoskeletal conditions was approximately $22.3 billion CDN, or roughly 2.1% of that country's GDP for that year, similar to the most recent of Rice's studies in the United States. In the Canadian study, indirect costs associated with earnings losses were much greater than direct medical care costs for these conditions. The initial study in the Netherlands is particularly instructive. In that nation, it was found that musculoskeletal conditions ranked second among all major diagnostic groups in medical costs, exceeding coronary and other circulatory conditions and only being eclipsed by mental retardation. In the Australian study,[31] costs were allocated to specific conditions, with the largest costs attributable to back problems and OA. Overall, costs amounted to AUS$55.1 billion.

The demographic structure of the developed nations in which these studies have been conducted are similar, with each facing a pandemic of musculoskeletal disease because of the aging of their populations. Increases are also probably associated with the increased prevalence of obesity in many of the developed nations; obesity is associated with OA. However, we are not aware of systematic studies of the cost of these conditions in the developing world.

## COST OF DISCRETE CONDITIONS

The first studies of the cost of illness for discrete rheumatic diseases were conducted about RA and, reflecting the importance of this condition in the practices of rheumatologists and other rheumatology health professionals, the economic impact of RA continues to be the subject of extensive investigation. However, a sizable literature on the economic impact of SLE and OA exists, and at least a few studies have been published about the costs associated with ankylosing spondylitis, psoriatic arthritis, gout, and fibromyalgia.

### Rheumatoid Arthritis

The costs of RA have been extensively reviewed,[39-46] most recently in a systematic review of 127 articles about all forms of costs[47] and another focused only the impact of productivity losses.[48] Several studies parse the literature for methodological differences among studies, including the perspective of the analysis the individual with the condition, focusing on the share of total costs paid out of pocket; payer, focusing on the share paid by health insurance plans or national health insurance; and society, focusing on all of the resources devoted to health care for the condition, regardless of who pays for those resources, as well as the forgone productivity; type of case studied (prevalent or incident); and effect of specific treatments, including but not limited to the biologic agents.

Among studies of RA not of recent onset and preceding the development of the biologic agents, direct costs in most studies were in the range of $5000 to $7000 per year, whereas indirect costs averaged between two and three times direct costs. Within direct costs, approximately two-thirds were attributable to hospital admissions, even though less than

10% of people with the condition are admitted to the hospital in any one year. Among those hospitalized, the vast majority received surgical interventions, primarily joint replacement surgery.

Among the approximately 90% of people with RA not admitted to the hospital in a year, costs in the prebiologic era could be quite low. The modal costs for RA in that era were $685 per year in one study, whereas the median was only $2715. At the 90th percentile, however, costs were higher than $8000 per year, while at the 95th percentile, costs were in excess of $30,000.[49]

The high indirect costs of RA are a function of the prevalence of work disability, with rates varying from a low of 34% in one study to a high of 59% in another.[50] One study reported on the duration of time from onset of the condition until work disability occurred. Of individuals with RA, 10% stopped working in the first year after onset, approximately half had stopped working in the first decade after onset, and 90% left work before the usual age of retirement.[51]

The impact of the biologic agents on costs of RA has been so profound that studies should be divided into those that predate and postdate the availability and diffusion of these agents. In some series, the proportion of people with RA receiving biologic agents has reached a third or more.[52] At approximately $20,000 per year per user, medical care expenditures for RA for biologic agents alone now exceed estimates of the total costs of the disease, including indirect costs, from the prebiologics era. Several studies quantify the incremental costs associated with the use of the biologics beyond what would be expected for people with similar health status. Michaud and colleagues[53] report that medical care costs for RA were more than $19,000 per year for patients taking biologic agents, but only approximately $6000 for those who were not, even after accounting for differences in the two populations. Fautrel and colleagues[54] reported that the incremental costs associated with etanercept and infliximab were approximately $23,000 to $25,000 per year, or more than three times the annual direct costs of RA in the prebiologics era. Sorensen and Anderson[55] studied the potential impact of the biologics on the Danish health care service, reporting that under varying scenarios, the biologics would raise the cost of treating RA from 50% to 500%. In a study of elderly people with RA, Weycker and colleagues[56] noted that RA care averaged between $12,000 and $23,000 in the biologics era, or more than twice the average from the prebiologics era.

However, perhaps the best way to gauge the impact of the biologic agents on the costs of RA is merely to note that, in this disease with a prevalence of less than 1% of the population, pharmaceutical companies find it profitable to advertise the agents on national television shows in the United States. Assuming that the prevalence was 0.5% of the approximately 250 million adults in the United States, or 1.25 million, that about a quarter of these used the biologic agents, and that the agents cost $20,000 per year, then biologic agents would account for more than $6 billion a year in health care expenditures for RA.

The costs of RA may be substantial early after onset. Merkesdal and colleagues[57] observed annual indirect costs resulting from lost wages within the first 3 years of disease. Of note, however, they observed that short-term sick leave costs were higher in the first year than the next two, but that permanent work disability costs increased to partially offset the decrease in sick leave. Similarly, Hallert and colleagues[58] reported that direct costs in the first year after diagnosis averaged almost $5000, whereas indirect costs were more than twice as high. Among individuals with seropositive RA of approximately 6 months' duration, Newhall-Perry and colleagues[59] reported that direct and indirect costs were approximately $200 and $300 per month, respectively. The relatively high indirect costs were a result of the high rate of work cessation (>10% among those employed at diagnosis) and sick leave (>5% in the same group).

The high medical costs associated with RA that manifest even among those of recent onset, present a paradox for choice of therapy at the level of the individual patient-provider dyad and at the level of the payer and society. On the one hand, there is ample opportunity to reduce much of the nonmedication cost of treatment for joint replacement surgery and for indirect costs resulting from lost wages by timely use of the newly discovered and highly efficacious biologic agents. On the other hand, iron clad evidence that they can reduce the frequency of joint replacement and work loss lacks information needed to prove cost-effectiveness. This lack of evidence stems in part from methodological problems in the studies conducted, including lack of head-to-head trials and uncertainty about the results of the studies that have been done.[60] Thus we know that the costs of RA are high and growing because of the use of biologic agents, but we do not know whether using them can reduce the indirect costs and the functional losses that lead to joint replacement surgery.

Although the bulk of the now vast literature on the economic impact of RA derives from clinical samples, it is possible to make an estimate for the United States as a whole by using MEPS data, with the caveat that there may be individual respondents to the MEPS surveys who are unaware of the specific form of arthritis they have, even though a physician would diagnose them with RA and, on the other hand, some who inaccurately state that they have RA. The advantage is that MEPS samples are from the community at large, eliminating the bias from sampling in tertiary care centers or select health plans. The MEPS estimates were made by merging five annual waves of data, from 2008 to 2011. In the United States, direct costs among individuals with RA averaged slightly more than $17,000 a year, whereas earnings losses among those aged 18 to 64 years totaled approximately $14,000 per year. In aggregate, direct costs and earnings losses associated with RA averaged $30.1 billion during the years the analysis was conducted, or approximately 0.2% of the nation's average annual GDP in those years.

## Systemic Lupus Erythematosus

The first studies of the costs of RA appeared in the mid-1970s; the first studies of the costs of SLE did not appear until almost two decades later. Nevertheless, there is now a substantial literature that spans three continents[61,62] and goes beyond studies of undifferentiated SLE to focus on the impact of specific levels of disease activity[63] and specific organ manifestations[64-67] on direct and indirect costs. A

comprehensive review of the literature on the economic burden of SLE has recently been published.[68] As we have seen, the costs of RA have been historically driven by work disability and joint replacement, but more recently expenditures for biologic agents have come to play an important role. SLE is also associated with high rates of work loss, and certain manifestations, particularly renal failure and neuropsychiatric impairment, result in high medical care costs because of hospitalization. However, the use of biologic agents in SLE is now only a prospect, so biologic agents are not yet a factor in the costs of SLE. The work loss costs may be profound in SLE, both because a high proportion of people with this condition experience temporary or permanent reduction of employment, and also because the age of onset is, on average, a decade earlier than in patients with RA.[69]

In the studies reviewed by Meacock and colleagues,[68] medical care costs ranged from a low of US$2214 to a high of US$14,604, with an average among the studies of approximately US$9000 per year. In an important study, Clarke and colleagues compared costs in the United States, United Kingdom, and Canada.[61] To ensure that prices for services did not affect their estimates, they used the same unit prices for each country. They observed that costs of SLE in Canada and the United Kingdom were of similar magnitude, but both were approximately 10% to 15% less than in the United States. This extra level of expenditure does not, however, result in better outcomes.

Indirect costs are measured by using a greater heterogeneity of methods than for direct costs, but for those using similar methods, indirect costs exceed direct costs by an average of approximately 2 : 1.[70] In the recent Meacock et al review,[68] the ratio of indirect to direct costs was approximately 1.25, with average indirect costs of approximately US$11,000 in 2010 terms. Indirect costs are high in SLE because of high rates of work loss; prevalence of work loss among those employed at onset of disease is estimated to be 15% within the first 5 years of diagnosis and 63% within the first two decades.[71] Even though these rates of work loss are certainly worthy of concern in their own right, the labor market outcomes of people with SLE may be worse than that of people with some other diseases of similar severity because symptoms such as fatigue, pain, and neurocognitive deficits may not be as obvious to the untutored eye and may affect the ability to work.[69]

In studies of the impacts of specific levels of disease activity and specific organ manifestations on direct and indirect costs, there is mounting evidence of the profound effect of lupus nephritis; other measures of renal damage; neuropsychiatric manifestations including memory impairment; and global measures of disease activity and severity and disease flare on costs. For example, in one study, Zhu and colleagues[62] observed that SLE patients experiencing flares incurred twice the total costs of SLE as those without flares, with those experiencing renal or neuropsychiatric flares having the highest levels of costs. Similarly, a study showed that work loss was more common among those with incident manifestations and higher levels of disease activity.[72] Clearly, effective treatment to prevent damage accrual to specific organs or to reduce the frequency and severity of flares may result in a substantial reduction in the costs of SLE.

## Osteoarthritis

Surprisingly few studies of the costs of OA have been completed. In part, this is because relatively few formal diagnoses are made of this condition relative to its "true" prevalence because treatment modalities would not change if a diagnosis were made. As a result, many of the costs of OA are subsumed within the broad groupings of "arthritis" and "musculoskeletal conditions." In addition, much of the costs of OA when they are enumerated are due to the side effects of nonsteroidal anti-inflammatory drugs (NSAIDs), including ulcers, or total joint replacement surgery. Another high-cost item is drugs said to decrease the prevalence of NSAID gastropathy, either gastroprotective drugs in concert with traditional NSAIDs or selective COX2 inhibitors that may be said to lower the frequency of gastropathy.[73]

Recently, Chen and colleagues reviewed the literature on costs of OA and found 11 studies.[74] In those studies, direct costs averaged approximately US$3100 in 2010 terms, whereas indirect costs averaged approximately US$4000. In the literature, it is clear that when hospitalization occurs for the complications of NSAIDs or for surgical intervention, average direct costs rise several-fold. Also, indirect costs enumerated are relatively small, because many people with OA are older than the normal age of retirement and thus are said to have no wage losses from the condition.

In the author's analysis of MEPS data, direct costs among individuals with OA averaged approximately $11,000, and earnings losses among people aged 18 through 64 years averaged approximately $7500. Aggregate direct costs totaled just under $340 billion, whereas indirect costs were about $121 billion. We also estimated the incremental costs experienced by people with OA compared with those of similar age and gender. In this estimate, aggregate direct costs totaled $62 billion and indirect costs totaled about $80 billion.

## Back Conditions

MEPS data are ideal for estimating the economic burden associated with back problems because the overarching category does not require a specific diagnosis from a physician but, instead, can be reported by an individual experiencing a back problem. With MEPS, the authors estimated that the prevalence of self-reported back problems increased by approximately 13% between 1996 to 1998 and 2009 to 2011, from 27.4 to 31.0 million, but the prevalence rate held constant, at 10.1% of the population.

Direct costs per case associated with back problems increased by approximately 68% during the period covered, from $4835 to $8150 in 2011 terms. This increase was fueled by a 167% increase in prescription medicine costs, in turn the result of an increase of 70% in the number of prescriptions filled per case and a 57% increase in the cost of each prescription. Earnings losses among individuals aged 18 to 64 years with back problems are relatively slight because a majority of people with back problems experience temporary rather than permanent disability. It should be noted that back problems are common causes of work loss, but that such loss occurs with relative infrequency compared with the high overall prevalence of back problems in the population.

### Ankylosing Spondylitis

Boonen and colleagues[75] have spearheaded efforts to characterize the burden associated with ankylosing spondylitis in a systematic review of the cost-of-illness studies in this condition and by an article describing the frequency with which various kinds of impacts for the condition are experienced.[76] In the former publication, they note that the total costs associated with ankylosing spondylitis including direct costs ranged between $7243 and $11,840, amounts comparable with the cost of RA in the prebiologic era. Woolf[77] observed that the typical individual incurs relatively high costs for assistive devices and personnel and sustains substantial earnings losses. However, the distribution among cost categories differs among countries. In the United States, coverage for physical therapy is relatively poor and hospital admissions are rarely reimbursed for ankylosing spondylitis, so a larger proportion of total costs of the condition are attributable to wage losses than in other nations.

### Fibromyalgia

Fibromyalgia, a controversial diagnostic entity, is defined by persistent, widespread pain and, perhaps, heightened reactivity to painful stimuli compared with those without the condition. Symptoms related to the condition include sleep disturbance and depressive mood. Fibromyalgia disproportionately affects women, many who are not employed for pay outside the home and others who, if employed, are subject to the normal discrimination in employment that women experience more generally. Annemans and colleagues[78] recently summarized the literature on the economic impacts of fibromyalgia; studies since their article was published corroborate the magnitude of the impacts they enumerated.[79-82] In the literature reviewed, direct medical care costs, averaging between $5000 and $6000, dwarf indirect costs due to earnings losses, which averaged between $2000 and $3000. This occurs despite evidence that a relatively high proportion of those who are employed at onset either stop working, reduce their hours, or at least may be subject to temporary disability. Others may change job tasks or switch jobs to accommodate the symptoms. Of note, the studies reviewed show that direct costs associated with fibromyalgia often spike before diagnosis because diagnostic testing accounts for a substantial burden on society but may be reduced while the diagnostic phase of care passes and/or the person with fibromyalgia accommodates to the condition or responds to the combination of pain medications and antidepressives that are often prescribed.

### Gout

Trieste and colleagues[83] recently reviewed the literature on the economic impact of gout, finding ten studies from the past decade. Since they finished their literature review, another study has been published,[84] the results of which are consistent with the summary from Trieste and colleagues. In the studies reviewed, gout is associated with an increment of between $100 and $1000 a year in direct medical costs beyond what would be expected of those of similar age. The strongest predictors of increased costs are increases in ambulatory and hospital utilization, but not prescription medications because most of the latter are not expensive drugs. Although the average increment in expenditures may be relatively small, one study of employees indicated that expenditures on behalf of those with gout were two times as great as those among a matched population. One study not included in the review by Trieste and colleagues reported on the costs associated with new cases of gout and observed that such cases had aggregate direct costs of $27 million in the United States in 2003.[85]

## CONCLUSIONS

Researchers use cost-of-illness studies to describe the impact of conditions on individuals and society (the positive function) and to assist policymakers in allocating resources to redress those burdens (the normative function). Some have criticized the development of such measures of impact because it deflects attention from assigning relative values to interventions that might alleviate the impacts (i.e., from calculating the cost-effectiveness of interventions regardless of the condition for which they are to be used).[86] In essence, they argue that the fact of presenting large estimates of burden may mean that resources may be diverted from using highly cost-effective interventions on conditions of small prevalence even when no effective interventions exist for the conditions of high prevalence and impact, in effect, wasting money.

However, an effective counterargument is that allocation decisions will still be made on criteria other than cost-effectiveness. For example, Verbrugge[87] long ago noted that fatal conditions tend to garner more attention from policymakers. This puts at a disadvantage groups with conditions with apparent low fatality rates but which are severely disabling. She observed that men tend to have higher rates of many fatal conditions, particularly cardiovascular disease, whereas women have higher rates of musculoskeletal and neurologic conditions that may have severe impacts but which are not commonly considered to cause mortality.

Certainly societies should allocate services on the basis of the return from the investment, but we must also be certain that we do not unduly discriminate against those with conditions that do not always garner attention proportional to their effect on people's lives. At the least, we must acknowledge the positive aspect of cost-of-illness studies in describing how resources that are diverted by disease could be used for other purposes were the disease to be eradicated, to provide a measure of the potential returns from effective interventions as they arise.

This debate about the role of cost-of-illness studies notwithstanding, there is no debating that musculoskeletal conditions do divert substantial resources from other uses and that the amount has been increasing because of the aging of the population and increases in the amount spent to treat them, especially for medications. Since the U.S. government began collecting MEPS data almost two decades ago, the gross economic impact of musculoskeletal conditions has grown by the equivalent of more than 4% of GDP, to 7.6%. If one accounts only for the increment expected of people of similar age and gender, the impact is smaller, but approximately a third of that total, not small. Musculoskeletal conditions do divert significant economic resources

away from other uses because of the substantial expenditures for medical care and by depriving the economy of the productivity at work and in other activities of those affected by the conditions.

CHAPTER 33

# Assessment of Health Outcomes

Dorcas E. Beaton • Maarten Boers • Peter Tugwell

**KEY POINTS**

- **Any single health outcome can give you only a particular view of the impact a disease has on a person. Make sure you have the right view for the purpose or question at hand.**
- **Core sets are minimal, but not exclusive, domains of outcomes that professional groups agree are important to include (if available) in all studies of a condition. They are available for several rheumatologic conditions.**
- **Defining and understanding what an investigator needs to measure is the key to choosing the right instrument.**
- **Choosing an instrument requires following a step-by-step process—looking for evidence of practical aspects of using the instruments as well as methodological/statistical properties.**
- **If the selected instrument lacks evidence of a certain property, the study can be performed to create the evidence rather than abandon the instrument.**

In an era of rising health care costs, greater provider accountability,[1] and an increased emphasis on measuring what matters to patients,[2,3] appropriate, high-quality instruments are needed for health outcome assessment. Researchers, industry, regulators, and clinicians are faced with the need to know what health outcomes to measure and how to measure them to be able to use that information in research, resource allocation, policy making, and clinical decision making. Initiatives in patient-centered outcomes research, such as Patient-Centered Outcomes Research Institute (PCORI), have shifted our usual view of health outcomes to focus on those of greater importance[3] to patients and their families so that results of clinical trials and other research will be more relevant and informative,[2,4] both to patients and to the realities of clinical decision making. Often this means including outcomes that are to the right side of frameworks such as the International Classification of Functioning, Disability, and Death (ICF)[5]: elements more attuned to functioning and participation in work and home roles, quality of life as well as symptoms, biomarkers, disease activity, and response.[6] It also means being open to new ways to understand familiar concepts. Hearing patients and their experiences has in the past created new understanding of concepts such as fatigue[7] or new instruments to capture a new understanding of osteoarthritis (OA) pain.[8] The more effectively instruments can capture our patients' experiences, the closer we will be to having the right set of tools in our arsenal.

Although the latter part of the 20th century saw the proliferation of instruments to capture outcomes such as health and quality of life, the last 10 to 15 years have seen advances in the standards for these instruments. Reeve and colleagues found 28 guidance documents associated with the selection of patient-reported outcomes (PROs).[9] Some standards, such as the U.S. Food and Drug Administration (FDA) guidance statement,[10] the European Medicines Agency (EMA) reflection, or the Outcome Measures in Rheumatology (OMERACT) Filter renewal,[11] define what evidence (measurement properties) is needed to be confident in the instrument to perform certain measurements.[12] Other standards focus on the appraisal and synthesis of studies on the performance of instruments, in efforts led by groups such as Evaluation of the Measurement of Patient-Reported Outcomes (EMPRO)[13] and the Consensus-Based Standards for the Selection of Health Status Measurement Instruments (COSMIN),[14] which outline methods for systematic reviews (search, appraisal, and synthesis) of studies of measurement properties. Still other efforts seek to standardize outcome approaches across studies. PROMIS (PRO Measurement Information System, www.promis.org), a federally funded initiative in the United States, has created a large item bank calibrated to the general population and is able to measure different health domains (including pain, function, depression) through computer adaptive testing (CAT). The predictability of patterns of response allow a small number of items to be used to focus on the score for an individual.[15] This has the potential to be a powerful tool to compare diseases or calibrate different scales onto a common metric. All of these efforts aim to put the best instrument in the user's hands and to provide consistent and high-quality data across studies to support the synthesis of findings and their application to clinical care.

In this chapter we will review a way to think about that need for an outcome measure and how to select the instrument to measure it. An outcome instrument is similar to a window in a building or home. It can provide only one view defined by its location, and its size (or, in the case of an outcome instrument, its content and response set). Deciding which instrument to use must logically begin with answers to the questions "What window do you want to look through?" and "What do you want to be able to see?" The clearer we can be about what we want to be able to measure in that situation, the easier and better the selection will be. Simple as it seems, answering these questions is often neglected in the selection of health outcome instruments. Once a good candidate is in hand, we move into a

decision-making process consistent with several other standards in the field but articulated here by OMERACT Filter initiative.[11,16] The Filter (now in version 2.0) is a set of criteria that need to be met to provide confidence that the instrument is the best to measure the target domain/concept. This is judged by accumulation of quality evidence of a set of measurement properties. This chapter addresses three questions: (1) What types of outcomes are measured in arthritis? (2) How do you know what you need to measure? (3) How do you find an instrument that can meet that need?

## WHAT TYPES OF OUTCOMES ARE TYPICALLY MEASURED IN ARTHRITIS?

In reading the rheumatology literature, and in monitoring the clinical care of patients, certain highly relevant outcomes will emerge. A group of these often emerge and are called "core sets" of outcomes.

### Arthritis/Disease Specific Instruments: The Core Outcome Sets

Core outcome sets are the minimal, but not exclusive, set of domains to be measured in a study of arthritis. They are usually recommended by groups such as OMERACT, The European League against Rheumatism (EULAR), the International League of Associations for Rheumatology (ILAR), the American College of Rheumatology (ACR), or groups formed around specific diseases, such as the Assessment for Ankylosing Spondylitis (ASAS) or the Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA). Various methods can be used to determine core sets, but the most popular are those based on consensus of key stakeholders (researchers, industry, regulators, patients, and clinicians) (OMERACT, Core Outcomes Measures in Effectiveness Trials [COMET]).[11,17] Core outcome sets (COS) standardize outcomes that should be used in each research study in a field, allowing greater comparability and less risk of bias associated with heterogeneity of outcomes in things like systematic reviews. Table 33-1 shows core outcome sets for clinical trials in nine types of rheumatologic conditions.[18-32] It also shows what each group recommends [R] as additional domains to be considered or that need more research before they become part of a set to be measured in every study. The first column shares the potential core areas and core domains suggested by the most recent OMERACT Filter 2.0.[11] OMERACT has boldly asked groups to ensure at least one outcome domain is covered in each core area (life impact, pathophysiologic manifestations, adverse effects, death and, optionally, resource utilization). The remaining columns show what has been selected for core sets in different rheumatic disease at present. There are many things in common: Most sets contain or recommend inclusion of pain, physical function, patient and clinician global assessments, and markers of inflammation. These should appear in any clinical trial or other research project in these diseases. Many also include disease activity and/or damage indices, which are often an aggregated clinical index of diverse clinical findings (joint count, acute phase reactants, and global ratings of severity) that reflect the activity of the disease at that point in time. Some core sets contain domains reflecting the unique aspects of the disease (e.g., spinal mobility in ankylosing spondylitis),[33] or the unique target of the study (e.g., tophi in measuring response in gout)[31] (see Table 33-1).

Although Table 33-1 focuses on the core outcome sets, in some cases an instrument choice has also been suggested, for example, the Health Assessment Questionnaire (HAQ) for disability in inflammatory arthritis (IA). In other instances, several options are provided. Strand reviewed six disease activity indices in lupus and found that they gave comparable results.[34] In some cases the domains are shared but the measurement technique varies within or by disease. In rheumatoid arthritis, the Disease Activity Scale (DAS) 28 uses 28 joints,[6] whereas in ankylosing spondylitis 44 joints are counted.[33] We will briefly review some of the more commonly encountered instruments used in arthritis, organized by the core areas described previously.

#### Indicators of Pathophysiologic Manifestations of the Disease

Disease activity is one of the most frequently measured concepts in pathophysiologic manifestations of the disease. One of the most commonly used indicators of disease activity (indicators of the inflammatory activity) is the DAS[35] and DAS28[6] in rheumatoid arthritis, in which a set of the core outcomes (i.e., acute-phase reactants, joint counts, and global ratings) are combined to form a weighted score that provides a score of 2 to 10 (DAS) or 0 to 9 (DAS28). Based on these scores, cutoffs were established to define high, moderate, and low disease states. Until recently, the low disease state (DAS28 <2.6) was considered an indicator of remission of arthritis and will be revisited later. Very recently, new criteria for remission in rheumatoid arthritis RA have been proposed. These new criteria recognize that disease activity is not always sensitive enough to perform at extremely low levels of functioning, leading others to refine scales or develop new ones to reach.[36] Other examples of disease activity indices (DAIs) include the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI)[37] and the six available for lupus.[34] When more than one is available, it is helpful to seek direct comparisons of instruments, such as that performed by Strand, to evaluate comparable information.[34,38] Work is also underway to focus on an evidence-based, consensus-driven definition for a flare-up or worsening of arthritis[39] to use in clinical trials to describe a worsening of the condition.

Damage indices are indicators of structural damage to joints, typically shown by joint space narrowing, erosions, subchondral cysts, or osteophytes. In rheumatoid arthritis, particular attention has been paid to this by Van der Heijde, who reviews three approaches (Sharp, Larsen/Scott, and Van der Heijde) that are used to assess joint damage and progression in joint damage by using change greater than the smallest detectable change around error.[33]

#### Life Impact of the Disease

**General Health Status.** Generic health outcomes provide information on an aspect of health across many conditions. Thus, theoretically, comparisons can be made of the burden of low back pain with that of arthritis or diabetes. This

depends on how well an instrument captures the burden in each disease group. Generic instruments have the advantage of allowing comparisons across diseases and of covering a broader range of health issues that may otherwise be overlooked in a core set (e.g., mental health). However, generic instruments, because of their breadth, tend not to delve sufficiently into the depth of experience in any one disease. As a result, they are often weaker in their ability to detect specific changes, and their sensitivity to different levels of disease activity may be low. They should, therefore, usually be supplemented with disease-specific instruments.[40] Popular examples of a generic instrument include the Short Form (SF)-36.[41] Direct comparisons of generic instruments have shown a surprising discordance in the scores across instruments.[42-44] Studies or clinical results may not be comparable if they use different health status scales.

**Utilities: Value of Health State.** Utility scales offer an overall score for the value of a health state, setting death at zero and full health at one. The emphasis is not upon describing the state, but on assigning a value, worth, or preference to that state.[45,46] Utilities are needed for economic appraisals in which the value of a health state is weighed against the costs of treatment. Utility states can be obtained by direct or indirect methods. Direct methods, such as standard gamble and time trade-off, involve the respondent working through exercises to elicit the value for his or her own health state against elements such as time, or more/less favorable health situations.[45] Indirect methods capture the state with standardized questions and then apply predetermined weights.[46] Examples include the EQ-5D, which is composed of five items (three response categories) combined to describe a health state. Similarly, the Health Utility Index (HUI) gathers information on six or seven dimensions of health (depending on the version) on five- to six-item response scales, to define a health state.[46] They, along with the increasingly popular SF-Six dimensions (SF-6D),[47] then use weights previously determined in different populations to assign the value to these health states, hence the "indirect" weighting. The absolute value obtained across these different approaches will vary.[45,48]

## Symptoms

Pain is usually measured by using a 10-cm visual analog scale or a 0 to 10 numeric rating scale of the intensity of the pain.[49] This simple instrument has been well tested and is easily understood by patients. However, Hawker led an initiative to better understand pain in hip arthritis, and found patients describing differences in their intermittent and constant pain. This resulted in a new instrument to be considered for pain.[8,50] Fatigue is another important symptom, which many patients feel is quite distinct from being "tired."[7,51] Teams are recommending either global indices or one of several available scales that were reviewed by OMERACT attendees.[52-54] In the area of sleep, work done through OMERACT on the measurement of the problem provides a recent strong example of moving through the concept of impairment of sleep, defining it, and then focusing on the available scales that capture that concept and definition.[55-56]

## Disability Scales

Physical disability is an example of a disease-specific measure of health status in arthritis because it is often affected and warrants a more specific instrument focused on arthritis. This is often measured by using the HAQ Disability Index (HAQ-DI),[57] which covers 20 items that examine different domains of daily functioning. Patients score each item on a 0 to 3 scale, in which 3 represents the greatest disability. Scores are obtained for each domain and then combined for a total score expressed on the same 0 to 3 scale. Scores are adjusted to a worse health state (a 2/3) if a support is used to complete a task. More details on the HAQ-DI are widely available in print and on the Internet. The HAQ is one of the "legacy" instruments that is fully linked with the PROMIS database.[15]

There are other scales or subscales that assess physical function, such as the Arthritis Impact Measurement Scale (AIMS)[58] and the AIMS2.[59] Others measure with even more specific foci, such as the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC)[60] or Knee Injury and Osteoarthritis Outcome Scale (KOOS),[61] which are the most commonly used scales for lower limb OA. The AUSCAN (Australian-Canadian) Osteoarthritis Index is an option for hand OA.[62]

**Self-Efficacy/Effective Consumer.** Self-management is becoming a part of programs for persons with multiple chronic conditions. For patients with arthritis, these programs have been shown to improve levels of self-efficacy: the confidence one has in one's ability to manage pain and disease effectively. Lorig's Self-Efficacy Scale is one of the most commonly used outcomes for this type of study.[63] Tugwell's group has developed a complementary "effective consumer scale," which captures the degree to which the patient is effectively managing his or her own health care decisions, interactions with the health care team, and disease monitoring.[64] It is an instrument with demonstrated reliability, validity, and responsiveness in arthritis, and has been a support for consumers with arthritis.[65]

## Work Disability: Looking Beyond Absenteeism

With the shift toward more aggressive management of earlier rheumatic disease, more people with arthritis are working, and outcomes that matter include their ability to manage at work.[26,51,66] Work is hard to measure because it forces us into considering the context of the disability: the job (hours, demands, flexibility) that will impact the presence at or absence from work as well as the difficulties experienced by the patient on the job. In work through OMERACT, more than 20 at-work productivity measures were identified.[67] Through 6 years of work with these tools, researchers winnowed through a review of content and conceptual focus to seven scales, and then reviewed or created evidence on the necessary measurement properties to satisfy the OMERACT Filter.[66,68,69] A slew of evidence was published that reported on multi-item and global scales. Correlations amongst these scales are still only moderate; however, they individually had accumulated a satisfactory amount of evidence to support their properties.

**Nonpaid Work Roles.** Participation in valued nonpaid roles, such as parenting, volunteer work, or leisure activities,

can be very important aspects of the burden of disease.[70] This concept will need to be considered carefully and outcome instruments reflecting this tested or developed in the future.

**Patient-Specific Indices.** Patient-specific scales allow the patient to nominate his or her own items, in effect creating their own outcome scale. Most researchers encourage three to five items to be nominated, often those that are most challenging for the person. A surprising number of these scales have been developed and reviewed by Jolles and colleagues.[71] Each taps very relevant content for patients, and because of this they can be responsive to change.[72] The challenge is in the mathematics and how to analyze the numeric score that has been created by different sets of items for each person. Analysis that focuses on individual-level quantification is likely best, for example, the percentage of people who reach their goal or improve in their selected activities.

### Toxicity/Adverse Events

Medical and nonmedical management of many rheumatic conditions carries a risk of toxicity and adverse events,[73] many of them unexpected. Because patients, clinicians, and policy-makers want to balance benefits versus harms when considering intervention, a comprehensive documentation of a range of adverse events is important in outcomes assessments separate from the treatment benefits.[10,74,75]

### Death

Rheumatologic conditions are associated with increased mortality, and arthritis-specific mortality should be monitored in arthritis research.

### Resource Utilization (Costs)

Costs associated with treatment (drugs, equipment, and physician visits) are all important in considering the benefit of one treatment versus another. Thus OMERACT Filter 2 includes resource utilization as an important but optional domain. Along with direct costs, indirect costs (e.g., lost productivity and caregiving) should also be considered, but can vary considerably. Harmonization is important to get a comparable estimate of cost across studies.[76]

This section has reviewed the standards that have been set to date. Many changes are underfoot with a renewed interest in patient-centered outcomes, and new domains and concepts are likely to emerge. The next two sections will help the reader to address the issue of wanting to measure something new, or deciding between different instruments.

## HOW DO YOU KNOW WHAT YOU NEED TO MEASURE? DEFINING YOUR MEASUREMENT NEEDS

Just as investigators define a research question before embarking on a clinical trial, so should users of health outcomes define a measurement need before choosing an instrument.[12,77] There are three parts to this definition: What, Why, and Who?

### What Do You Want to Measure?

It is important to have a sense of the concept you want to measure before you choose an instrument. This way, you will be sure to choose an instrument that meets your needs, and you will be less swayed by what the developers say is measured. The use of theory or, better yet, patients' own experiences can help clarify the scope and content of an ideal measure of elements such as recovery[78] or fatigue[54] and complement the view of the researcher. This understanding can only help with the selection of the best instrument, scientifically and from the perspective of the relevance of the scores for our patients.[79,80] Groups such as EULAR or the FDA have named the direct involvement of the patient in the development of patient-reported outcomes an essential feature for new scales,[10] (for example, as seen in the development of Rheumatoid Arthritis Impact of Disease [RAID]).[81] Involving patients in this role as research partners may have challenges in communication and research nomenclature,[82] but the benefit in terms of understanding the concept you are trying to measure (the "what") is unmatched.

Defining key concepts or outcomes may also be facilitated through use of a conceptual framework because they define key concepts/constructs and their theoretical relationships. One increasingly popular framework is the International Classification of Functioning (ICF), endorsed by the World Health Organization in 2001.[5,83] It describes three main concepts (Figure 33-1): (1) impairments (symptoms, structural limitations), (2) activity limitations (difficulties while performing tasks), and (3) participation restrictions (social role participation). Around this the ICF adds the importance of environmental factors (job demands, environmental barriers, weather) and personal factors (predispositions, coping strategies). OMERACT made use of the ICF in formulating the core domains of measurement in Filter 2.[11] Choosing a framework that helps you to define and think about the concept you wish to measure will be very helpful down the road when you try to understand your findings. They form the basis for understanding your observations, testing hypotheses, or planning and executing an analysis. Thinking about your concept and defining it carefully and explicitly should be done before any instruments

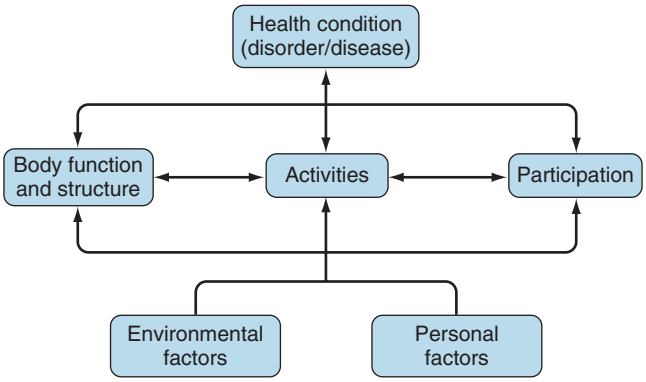

**Figure 33-1** The International Classification of Functioning (ICF) conceptual framework showing the hypothesized relationships between domains of impairment, activity limitations, and participation restrictions and the direct influence of environmental and personal factors on these domains.

or core sets are reviewed. The instrument should meet the need, and not the reverse.

### Why Are You Measuring?

Clarity about how you intend to use the scores from an instrument and define the intended purpose is needed.[12,77] Kirshner and Guyatt describe three purposes: descriptive (measurement of a concept at one point in time, such as the burden of illness [i.e., this group is sicker than that group]), predictive (provide information about the future, such as the HAQ's ability to predict mortality in arthritis), and evaluative (measure change during time, such as the benefit or harm from treatment).[84] This intended purpose will define the measurement properties you need to establish to ensure the instrument is suitable. In this chapter, we focus on the purposes relevant to health outcome assessment: describing an endpoint state in a trial at one point in time (Kirshner descriptive purpose) and evaluating the amount of change experienced during time (Kirshner evaluative purpose[84]).

### Who Comprises the Target Population?

The target population is critical, but often overlooked. A given instrument may, for example, work very well in severe OA of the hip but not be sensitive to the early symptoms of the disease. It is equally important to consider if you want to measure for an individual patient or for describing a group of patients as a whole, for example, in a clinical trial. The former demands much higher levels of things such as reliability (precision), such as a coefficient of greater than 0.90 as opposed to minimum 0.75 to 0.80 for group-level applications.[85]

The measurement need is defined by the concept, the intended use of the instrument scores (the purpose) and the population. All need clear definition before any attempt to decide on an instrument for that concept of interest in that context of use. Much of that decision making will be based on a well-defined need.

## DECISION-MAKING INSTRUMENT FOR SELECTING THE OUTCOME THAT CAN MEET YOUR MEASUREMENT NEEDS

Armed with a well-articulated need, the selection of an outcome is a set of steps. Failure at any one of the early steps would quickly suggest it is time to choose another candidate instrument. Failure of a missing measurement property is a flaw, but is often correctable with additional study. There are many guidelines for selection available, particularly for the acceptable levels of reliability and validity, that offer more detail than can be provided here.[9] What we will describe here is a decision-making process that can be used to assess whether a given instrument fits with the articulated measurement need. This process, depicted in Figure 33-2,

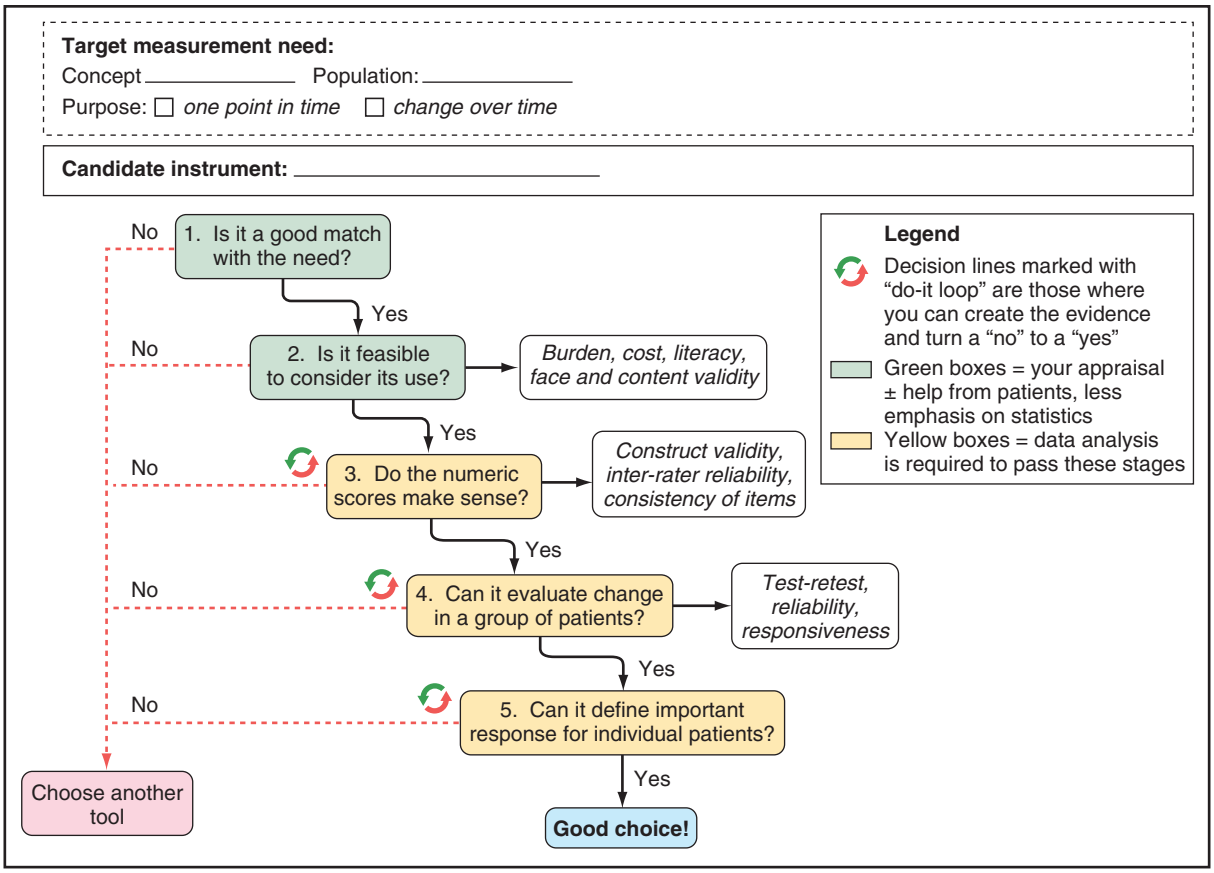

**Figure 33-2** Algorithm showing the decision-making process for the fit of a candidate measure with your target measurement need. The first two *(green)* boxes can be completed by appraisal of the instrument, hopefully with input from respondents. The last three *(yellow)* boxes require data. Many instruments are weeded out as a poor fit in steps 1, 2, and 3; things that cannot be corrected. The *"do-end" loop* denotes stages at which you can pause to create evidence if it is missing and do not necessarily have to abandon the instrument.

builds on the work of Law,[86] Lohr,[87] Mokkink,[14] Reeve[9] and the OMERACT Filter[88] as well as highlighting key concepts in each area from the published works.

This decision-making process has three key features that deserve attention. First, it always starts with a firm statement of the measurement need (and a search for all candidate measures). Second, much work must be done with a user's guided reflections on what they think of the instrument itself, including, if possible, feedback from patients before the correlations and effect-size statistics are viewed.[69,89] A common misconception is that measurement has to do with statistics, whereas much has to do with common sense. Third, the inability to confirm each of the earlier stages indicates an irreconcilable mismatch and suggests that you are better off finding another candidate instrument. Conversely, if you have made it past this prestatistical appraisal and you still have a candidate measure, you are likely holding a good scale, and may want to create any missing evidence on its measurement properties as opposed to abandoning it for their lack (*do-it loops* in the diagram). With these overarching points in mind, let us look at the process.

## Step 1: Is It a Good Match with Your Needs?

Think about your concept and then decide, based on the description of the candidate instrument and the nature of the items, whether there is a match between the instruments concept and the measurement need (concept, population, purpose).[77] An operational definition of the target concept, the applicable populations (specific patient graph or general population), and intended purpose should be articulated by the instrument's developer and should match your current need.[10,87,90] If these elements are not there, or if the instrument is not a good match, start with another candidate instrument.[91] For example, your target might be physical function, and the instrument might only briefly cover physical function and include much more detail on emotional and social health than even is in use in your research community. For you, if the concept is not a clear match with your target, pass it by.

## Step 2: Is It Feasible to Use?

Feasibility covers the practical aspects of using this scale in the intended setting.[86-88] Does it take too much time? Are the licensing costs too high? Does it require special equipment? Is it too burdensome for your patients (e.g., language, literacy, acceptability of questions)? Is it well-formatted, and do the responses and scoring make sense given the target and the question? Are the questions phrased in a clear and simple manner? Are the necessary scoring instructions available? Are the results of the score easily interpretable? A negative response to any of these questions could direct you to another, more feasible instrument. Feasibility often makes or breaks a decision about a candidate instrument.[88,89] Others might call this "sensibility" or "clinical usefulness" of an instrument. Usually the appraisal is completed by the investigator, but additional insight can be gained by including patients' input about the length, difficulty, and burden of the questionnaire or by their response to it (floor/ceiling effects).[89]

### Content Validity

Does it appear that the candidate instrument covers the domains of your concept well, and do the items align in this content and/or domains? It now becomes clear why your measurement need must be well articulated before this point to avoid an exercise in circularity. This, like step 2, is usually done by the clinicians or researchers, but patients can also provide valuable insight into ensuring the content is comprehensive.

Content validity appraises the items and domains of a scale, and whether the authors have covered the breadth and depth of the concept.[85] In other words, are all the important areas, covered, and is there enough depth to capture the range of experience of the patients you wish to administer it to?

## Step 3: Do Its Numeric Scores Make Sense? (Construct Validity)

Having convinced yourself of the content and practical feasibility of this scale, the next step begins the more data-intensive evaluation.

### Item onto Scale (Only for Multi-item Reflective Scales): Structural Validity

The first phase is at an item-to-scale level: The gathering of data on whether the scale at an item level is performing in the manner it should. This is often called *structural validity*, confirming the structure of the items on their subscales against the developer's expectations. It bridges content and construct validity and is often aligned more with content, but is considered here because of its dependence on data and its analysis. It is assessed through approaches such as factor analysis (if the instrument was designed to have multiple items aligned with one underlying trait) or item response theory[92,93] to assess whether the items designed to capture consecutive levels of the trait along the continuum are doing a satisfactory job. It should be noted that factor analysis will favor multiple items that are endorsed in a similar manner across them. These will be highly correlated. The goal of factor analysis is to see whether similar items are sufficiently correlated to suggest they are eliciting consistent patterns of response across people. If there are multiple subscales, then these will separate as different patterns of response, with more correlations between items within its subscale than items across subscales. It all makes logical sense and is summarized mathematically by inter-item correlations, item-to-total correlations, and factor analysis.

If another approach, such as item response theory (IRT), has been used in selection of items for a scale, then a wider range of less highly correlated items will be selected to capture all levels of the latent trait, which would not be summarized well by traditional factor analysis. The approach used needs to match the approach used in development. IRT-based instruments need to have structural validity assessed within modern measurement approaches, using IRT-based methods, perhaps checking the stability of the items and their ranking/weight across disease severity or disease type (differential item functioning). One form of

IRT is the simplest Rasch model. It stands as a template for linear measurement of a single dimension, so when the Rasch fits, those items are confirmed as representing an underlying trait, confirming its structure. In other forms of IRT, the model is adjusted to fit the data rather than changing the scale (as in Rasch), and model fit in a new sample and/or stability across different groups is used as confirmation of the structure of the scale.

### Score Level Analysis: Construct Validity

The next step is to explore data to see whether the instrument's numeric scores make sense and behave in the same way we would expect an excellent instrument of this concept/domain to behave. Confidence with construct validity should be established regardless of the eventual purpose (descriptive or evaluative) because it answers the question of whether or not the tool measures what it says it should measure. Sometimes it is de-emphasized in evaluative instruments in favor of a more detailed evaluation of change and responsiveness; however, others (including these authors) stress the importance of ensuring you know what you are measuring before focusing solely on change scores.

Construct validity is generally measured by comparisons with similar scales or related constructs (i.e., high and low levels of pain and function). Theoretical situations are established *before* analysis, the direction and magnitude of the expected relationship declared, and then the relationship is tested.[77,87,91,93] Ideally, testing with scales expecting high correlations, and also no correlation will provide more confidence in what this tool is measuring. Comparisons should also be made among groups known to differ (high vs. low severity); known groups construct validity. Again, this is based on an a priori theory to check whether the instrument is measuring what it is supposed to measure.[91] If the evidence is not available, or is not available for the intended context of use, you have a choice to abandon the instrument or conduct a study to create that evidence, and then continue to advance.

As well as understanding construct validity, precision of measurement is also important. Again, for more psychometric, reflective multi-item scales, this comes in the form of a check of the consistency of responses across items by using Cronbach's alpha coefficients, or its equivalent Kuder-Richardson Formula 20 if the scale is dichotomous (yes/no). In IRT-based scores, the same idea of precision is reflected in a person separation index (PSI). High cross-sectional precision suggests that the true score lies within a tighter smaller range around the calculated or observed score (margin of error). Internal consistency coefficients lie between 0 and 1. Higher is generally better, although coefficients higher than 0.95 suggest redundancy in the items, and if burden is a concern, it might be desirable to drop some items. The internal consistency reliability can be converted back into the scale score by calculating the precision limits (by using 95% limits, the true score list somewhere within $1.96 \times s[1\text{-}r]^{1/2}$, where r = internal consistency and s = standard deviation). This tells us the range within which the true score for an individual will reside. This is not a feature of a scale containing weighted sums of different attributes, such as disease activity measures.[94]

If more than one person will be gathering the data, interrater/observer reliability should be measured and quantified with an intraclass correlation coefficient (ICC) for continuous measures or a weighted kappa for ordered categories.[95] This would be important for either IRT-based or summed multi-item scales as well as more observer-based tools of clinician-reported outcomes or clinical indices (disease activity indices). There are different types of ICC, depending on the model used for the variance estimates. The type of ICC should always be named.[95] The ICC and weighted kappa assess how well the instrument reproduces the exact same score across observers, and are preferred versus correlation coefficients that look only for trends and not a direct match in numeric values. Cutoffs are always challenging, but, in general, reliability should be at minimum 0.75[85,87] for group-level analyses (in which analysis is always done for a group of patients, as in the mean score comparisons in a clinical trial). For description of an individual patient or making decisions about their care, ICC should be 0.90 to 0.95.[85,87]

## STEP 4: CAN THIS INSTRUMENT EVALUATE CHANGE DURING A PERIOD OF TIME IN A GROUP OF PATIENTS?

After getting a general sense of the construct validity of the instrument, we sometimes wish to know whether this outcome is able to measure change during a period of time. This is only important if you are going to measure and make claims about a *change* in score (i.e., if a change of 50 points was observed). If your goal is to describe an outcome, such as the level of pain after a treatment, you may have enough information at step 3. In the original OMERACT Filter, this was the "discrimination" component of the information need in Filter 2. This is expanded and contextualized to answer the question "Can the instrument discriminate well enough to detect the change you need to be able to detect?" The hallmark of the ability to measure change in a group is twofold: First, do the scores remain the same when the target concept has *not* changed during a period of time (test-retest reliability), and second, when the concept changes, does the score on the instrument change as well (responsiveness or sensitivity to the target construct of change)?

### Test-Retest Reliability

Test-retest reliability requires two administrations of the instrument during a period of time when no change in the target concept has occurred. As a reader of reliability studies, you should feel convinced that no change in the target (e.g., pain, function, or disease activity) would have occurred in these patients in this situation.[14,96,97] Often, people conducting studies of test-retest reliability will establish a clinical situation in which no change should have occurred, or they use an external anchor (e.g., a question about whether the patient's pain is the same as last time) to find patients who have not changed. Similar to interobserver reliability, the ICC is the preferred statistic for continuous scores and weighted kappa, its equivalent, for categorical scores.[95] The cutoffs are the same, and a coefficient can be converted into

a "minimal detectable change"[98] = $1.96 \times s(2[1\text{-}r])^{1/2}$, where s = standard deviation and r = test-retest reliability (ICC).[85,98] Ninety-five percent of people who are stable will have change scores less than this value, hence a change greater than this is not likely to occur in a stable patient. This becomes a lower boundary of meaningful change. Anything below that boundary could be simply day-to-day fluctuations in scores.

Responsiveness is perhaps best thought of as longitudinal construct validity. Similar to construct validity, it depends on an a priori theoretical relationship in which the attribute is changing with time (e.g., change in pain with time). We all too often focus on the amount of change recorded, rather than the match of the change in the instrument's scores with the type or amount of change that has actually occurred and was expected in that testing situation. A large change is not useful if we were expecting a small one; it only suggests error and noise. The amount of change expected in a study of responsiveness should be carefully described and should be directly associated with the intended application (i.e., measurement need).[99] If the goal is to detect change in a clinical trial, then it is important to assess the instrument's ability to detect the difference in change between treatment and control groups. If the goal is to detect change in a cohort, it might be more useful to examine change in a single group, perhaps in a treatment of known efficacy that is close to your intended application (e.g., hip replacement) or in people who rated themselves as improved on an external anchor (e.g., global index of change). Responsiveness is summarized with statistics of signal (change) overnoise (error) such as the standardized response mean (mean change/standard deviation of change), *t* statistic (mean change/standard error), or effect size (mean change over standard deviation of baseline).[95] These statistics on their own have little meaning without an a priori construct of change (magnitude and direction expected).

When the target application is the quantification of the relative change between treatment and control groups, such as in a clinical trial, the ability of a scale to discriminate at that level, and against similar groups as in the target application, is needed. The effect size of statistics described above can be adapted for relative change between two groups[72,100] or a standardized mean difference can be calculated.

Deyo also described the correlational approach (correlate change and another indicator of change) as a direct parallel to cross-sectional construct validity.[101] He also suggested a receiver-operator characteristic curve approach (various change scores against external gold standard that the person change). This offers information on the sensitivity and specificity of different change scores for application to individuals as well as the area under the curve as a summary of discrimination between changed and unchanged groups.[101] All of these approaches are dependent on the external anchor of change having occurred, and this is an important part of the study. Regardless of the approach, the numeric summaries of responsiveness, such as effect sizes or areas under the curve, should correspond to the type of change (magnitude and direction) expected in the a priori theory. A large effect size or area under the curve does not mean an instrument is to be stamped as "responsive." It should correspond with the change anticipated in the study, small or large. Comparisons of the effect sizes are helpful if different instruments are compared in the same study, as was done by Buchbinder[72] or Verhoeven[100] in early IA patients. But caution should be used when comparing instruments across studies. Responsiveness is a highly contextualized property, and the same instrument may not be responsive in another situation (early vs. late disease, OA vs. IA, 2-week vs. 6-month follow-up).[87]

## STEP 5: ARE THRESHOLDS OF MEANING DEFINED FOR THIS SCALE?

The final step, often deemed the most elusive,[102] is the interpretability of the scores. Responder analyses that quantify outcome as the "proportion" improved, recovered, or who have responded to therapy are classifying and counting individuals who have responded or not[10] and although misclassification error might not affect the proportions in one group relative to another, they do impact clinical decision making for one patient. The intended application should be considered.

### Benchmarking States

At the end of a trial, a patient's pain is at 2 of 10 on a pain scale. Is this a good outcome? The meaning of different scores on an outcome assessment is used both for classifying people at the beginning of a trial and at the end (final state). To establish the meaning of the specific values of an outcome scene, comparisons are made with other known health states, such as severity indices, ability to work, or self-rating as mild.[103] Gradually, enough trends might be seen across different scenarios to gain confidence in the meaning of "good" or "mild."[78,104] In rheumatology, we see the emergence of low or minimal disease activity states (LDAS; MDA),[105-107] patient acceptable symptom states (PASS),[108] or remission criteria with the DAS28[38] as thresholds below which people are considered to be in an acceptable state (defined as either tolerable symptoms or disease activity that does not require medication changes). At this point these thresholds are being established, and similar to change thresholds, we may find variability in the values[38] that will need to be sorted out with methodological work and application in clinical practice.

### Changes in State

The second type of interpretability concerns change scores.

#### American College of Rheumatology Response Criteria

The American College of Rheumatology (ACR) took the core-set measures and determined that if one observed an XX% change in joint count, swollen joint count, and in at least three of the following: (1) erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP); (2) physician global, patient global, pain, or (3) physical disability, then one had a clinical response, and the individual would be classified as a responder. The percentage (XX%) is usually 20%, but 50% and 70% have also been considered. The

ACR20 is widely used, defining responses across a wide variety of domains, and discriminates well in clinical trials.[100]

### Minimal Clinically Important Differences/ Improvements

Defining the threshold of change above which a person has had an important shift in outcome is what Kirwan has described as the "elusive crock of gold at the end of the rainbow."[102] Nevertheless, important advances have been made. In 2000, Wells described nine different methods for deriving minimum clinically important differences (MCID) from the literature.[109] Some use distributional cutoffs (e.g., 1/2 standard deviation(s), or effect size of 0.2 or 0.5),[110] which have been criticized as lacking any meaningful anchor. Others are dependent on an external anchor, which indicates that important improvement has occurred, but are sometimes challenged by their dependence on that anchor as well as on the perspective of the person who determines the response (patient, doctor, payor). MCIDs repeatedly have been shown to vary with baseline state[111] and with improvement versus deterioration,[112] mandating that they are looked at separately.[113] In MCID work, one should plan on working with a range of values as a result,[114,115] rather than one absolute. It is also important that the testing situation and the study design (kind of change, anchor for change) are similar enough to your intended use that you can be confident in the results.

### Combined Approaches: Change and State

An attractive, although often overlooked option, is to combine the last two approaches. In 1996, EULAR defined clinical response as a change in DAS28 score of more than 1.2 (change), plus a final DAS28 score of less than 2.4 (final state).[35] Jacobson did the same in defining response to psychotherapy; change greater than error was induced by care (change > error [MDC]), plus a final "normal" state.[116] This combination has been echoed by studies of how patients define being "better."[78,104,117] Both change and landing in a good state would be required.

The approaches described above focus on interpretation at the level of the individual, perhaps for use in clinical practice or in a response-type analysis of a clinical trial or economic appraisal (% responder). Verhoeven has shown that the same instrument may not perform equally well in a responder-type of analysis and for a group-level change.[100]

At each stage of this appraisal, there is an element of judgement. There will likely never be perfect evidence across all stages. The user will need to assess the potential risk of accepting less than ideal evidence, or abandoning the scale. They may also, however, *create* the evidence by doing it themselves. An instrument that makes it through this appraisal is likely a good fit with the measurement need. Anything short of that could lead to error and be prone to misinterpretation. By working from top to bottom on the figure, instruments that are not targeting the right concept or are impractical to use in the intended setting can be quickly eliminated before extensively reviewing the literature for the measurement properties.

## AREAS OF GROWTH IN HEALTH OUTCOME ASSESSMENT

### Systematic Reviews of Measurement Properties

With the growth in the number of articles published on measurement properties for a given tool, we are seeing the growth in the number of reviews and, more recently, systematic reviews of the literature ($n$ >489, www.cosmin.nl). By systematic, we mean standardized methods for searching the literature, selection of articles as relevant, critical appraisal for risk of bias, and synthesis. There are several approaches recommended; however, COSMIN is a valuable resource both for search strategies and suggestions for a scored critical appraisal instrument (not risk of bias). There are many critical appraisal tools available, most focused on quality of reporting and quality of methods versus risk of bias. Similar to a systematic review of intervention studies, a lot of work is involved in systematically reviewing the articles for each measurement property. But this process can be streamlined by returning to the points we have emphasized above: first that you don't need to go that far if you do not have a match for your concept, and second, there are good- and bad-quality studies of any measurement property that we need to weigh differently in our decision making. Unlike systematic reviews of intervention studies, those for measurement properties are actually several parallel reviews, one for each property.

### The Message Could Be in the Subgroups: The Rise of Cluster Analysis to Uncover Patterns of Responses

Clinicians and researchers are always trying to maximize the understanding they can get from their outcome measures to capture the true experiences of patients. In recent years we have seen emphasis placed on looking for patterns of response in patients rather than mean change alone. This type of analysis needs at least three measurement points and a large sample but allows subgroups such as "quick responders" versus "unchanged during a period of time" to be identified. This latent trait clustering of these longitudinal data points allows new insights into types of response, or, likely, ongoing course. It makes a great deal of clinical sense, with clinicians recognizing patterns such as a quick, sustained positive response over time in contrast to a patient with a slowly progressive deterioration in function. These types of patterns can only be captured with longer follow-ups, and this latent class analysis.

### Adaptation to an Ongoing Disease

In this chapter, we have focused on the measurement of health states, and indeed their improvement or deterioration over time. However, people with chronic diseases will successfully adapt to ongoing disease with behavioral strategies, or cognitively reshape their idea of what "good health" means.[118] These are things that are sometimes induced in our patients while therapists try to help them deal with the impact of the disease. In some circles this is called "adjustment,"[117] in others "response shift."[119] The challenge in

health outcomes assessment is that this type of outcome will not be captured well in a pre-post change score. A number of groups are researching how to incorporate adaptation into our health outcome assessments.

## CONCLUSION

Patient-centered care initiatives, such as patient-centered outcomes research, have brought a lot of attention to the topics raised in this chapter. A commitment to outcomes that matter, and increased rigor in the standards these measures must achieve to be used in clinical care or labeling means that the coming years will see even more advances and choices in health outcomes measurement. Standardized sets are not meant to restrict a researcher's outcome choice but rather to open doors to increased comparability across studies, interventions, and patient experiences. Trends in RA mentioned in this chapter show an increased use of core sets since their release, thus allowing for more confidence in the results of a synthesis.

Testing instruments to make sure they are good metrics for a given measurement need (as defined by the target concept, population, and purpose) will become more deliberate and more focused on assessment of whether the tool works. While the research and clinical communities move to this level, our instruments and our ability to make use of their scores will get better and better.

The field is on the brink of deciding the role to be played by item response theory and computer adaptive testing in widespread care settings. Improved access to PROMIS and networking platforms that will arise from PCORI will help to facilitate this. However, despite progress in assigning a numeric value to a complex health state, a healthy struggle continues with the interpretability of scores. What does the numeric score mean in the real world of patient-clinician decision making? It is not always a simple translation from questionnaire score to clinical meaning. Health outcome assessment is well advanced in arthritis care, and we thankfully acknowledge the years of work and commitment of many professional and patient/consumer groups. Advances will continue in the use of technology, the breadth and depth of our outcomes, and the quality of measurement methods while the field of arthritis outcome measurement strives to keep pace with the needs of patients and their families, clinicians, researchers, and policy makers.

CHAPTER 34

# Biologic Markers in Clinical Trials and Clinical Care

David L. Boyle • William H. Robinson

**KEY POINTS**

- Biomarkers can facilitate the diagnosis, stratification, and therapeutic management of rheumatic diseases.
- Biomarker validation requires careful demonstration of utility in multiple independent data sets
- Actionable biomarkers can guide therapy and clinical decision making.
- "Mechanistic" biomarkers are based on disease pathogenesis.
- Predictive and pharmacodynamic biomarkers can facilitate drug development by identifying the individuals most likely to benefit and by providing an assessment of response.
- Surrogate biomarkers can be used in regulatory processes for drug approval.
- Multiplexed biomarkers could offer increased utility compared with individual biomarkers.

Drug development in rheumatic diseases has primarily relied on clinical endpoints, such as mortality, joint damage, or other easily quantified metrics.[1] Clinical trials focused on these parameters often require very large numbers of patients, are underpowered for early "go, no go" decisions and require very long time lines.[2,3] Similarly, patient care in rheumatology typically utilizes a combination of traditional evaluation approaches that integrate standard laboratory tests with clinical assessments.[4,5] A pressing need to integrate laboratory or imaging methodologies in the clinic and drug development has emerged, especially to help stratify patients and individualize therapy.[6,7]

To address this need, a concerted effort to develop novel biomarkers has gathered momentum. Although many definitions of biomarkers exist, one of the broadest and most relevant was provided by the U.S. Food and Drug Administration (FDA): "Biological marker (biomarker): A characteristic that is objectively measure and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention."[8]

Some biomarkers are used routinely in clinical practice, such as C-reactive protein (CRP) to assess disease activity or liver enzymes to monitor drug toxicity.[9,10] Imaging technology can evaluate synovitis, as with power Doppler ultrasound.[11] Genomics studies could ultimately be integrated into clinical evaluation to help personalize therapy.

Biomarkers are divided into a variety of categories based on their application, including susceptibility, exploratory, proof-of-concept, and many others.[12] One category of biomarker requires true validation, namely, the surrogate biomarker. A surrogate biomarker is a test approved by regulatory authority as an endpoint that can be used in place of a clinical outcome for drug approval.[13] For example, decreases in hemoglobin A1c are sufficient for regulatory approval for a diabetes drug. In rheumatology, changes in radiographic joint damage can be used for a "disease-modifying" claim in rheumatoid arthritis rather than joint replacement surgery.[14] On the other hand, other measures such as magnetic resonance imaging (MRI) or ultrasound, might not be accepted and have not been sufficiently validated for regulatory authorities.[15]

## MOLECULAR BIOMARKERS

Molecular biomarkers are biochemical variables that include measurements of proteins, RNA, lipids, carbohydrates, metabolites, and other biomolecules in the blood, other biologic fluids (e.g., synovial fluid) or tissues. Molecular biomarkers can be objectively measured through a variety of techniques, and can be indicators of normal or pathologic processes, or can be indicators of response to therapy.[16] The advent of large-scale nucleic acid sequencing, other genomics, proteomics, lipidomics, glycomics, and metabolomics technologies have enabled the identification of next-generation molecular biomarkers. Examples of molecular biomarkers related to autoimmunity and inflammation are shown in Table 34-1 and discussed in detail in the following text.

### Characteristics of Biomarker Measurement

Molecular biomarkers are measured using a variety of specialized assay platforms, and the performance characteristics of the specific assay largely determine the utility of the assay. Key characteristics include sensitivity, specificity, predictive value, and assay reproducibility.[17] Whenever possible, transition of candidate biomarkers from a discovery platform to a clinical grade test can significantly improve the performance characteristics of a biomarker. For example, mRNA biomarkers can be initially identified by using DNA microarrays or RNA-sequences that detect very large numbers of RNA transcripts in each experiment but are limited in assay reproducibility. As a result, for use in clinical medicine or in clinical trials, narrower assays such as quantitative polymerase chain reaction PCR (qPCR) assays are frequently developed to enable robust and reproducible measurement of a select set of mRNAs with utility as predictive and/or

**TABLE 34-1** Examples of Molecular Biomarkers of Autoimmune Disease*

| Type of Biomarker | Biomarker | Use of Biomarker | Data Source |
|---|---|---|---|
| Cytokine | IL-7 | Prediction of responsiveness to IFN-β in MS | Retrospective testing in samples from clinical trials |
| Chemokine | CXCL13 | Assessment of disease activity in RA<br>Prediction of disease progression in RA<br>Assessment of response to TNF blockade<br>Prediction of the rate of B cell repopulation after rituximab therapy | Retrospective testing in samples from clinical trials |
| Cell type | Th1 cells, Th17 cells | Prediction of responsiveness to IFN-β in MS | Retrospective testing in samples from clinical trials |
| Autoantibodies | ACPA | Diagnosis of symptomatic RA<br>Diagnosis of asymptomatic RA | Clinical practice<br>Retrospective testing in samples from clinical studies |
| | ANA | Diagnosis of symptomatic SLE | Clinical practice |
| Signaling molecule | Erb2 | Prediction of responsiveness to anti-ErbB2 monoclonal antibodies and to tyrosine kinase inhibitors in breast cancer | Clinical practice |
| Gene expression | Wound–healing signature | Identification of women with breast cancer who do not need adjuvant chemotherapy | Retrospective testing in samples from clinical studies |
| | IFN-α/β-inducible gene signature | Assessment of the efficacy of anti–IFN-α monoclonal antibody therapy in neutralizing IFN-α and downstream signalling in SLE | Prospective testing in clinical trials |
| | Imatinib-responsive gene signature | Identification of systemic sclerosis patients most likely to respond to treatment with the tyrosine kinase inhibitor imatinib | Retrospective testing in samples from clinical trial |

*Outlined are molecular and cellular mechanisms involved in the initiation and progression of autoimmune responses in rheumatoid arthritis (RA) and other autoimmune rheumatic diseases. The molecules, molecular pathways, and cellular responses outlined can be measured as biomarkers for characterization of RA and other rheumatic diseases.

ACPA, Anti-citrullinated protein antibodies; ANA, anti-nuclear antibodies; CXCL13, C-X-C motif chemokine 13; ErbB2, receptor tyrosine-protein kinase ErbB2; MS, multiple sclerosis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; Th1, T helper 1 cell; Th17, T helper 17 cell; TNF, tumor necrosis factor.[35]

pharmacodynamic (PD) biomarkers. In rheumatology, such an approach is illustrated by the discovery via DNA microarrays and clinical implementation with qPCR of a type I interferon mRNA signature to predict the response to rituximab in rheumatoid arthritis (RA).[18]

Assays have two fundamental characteristics[19]:

- *Accuracy*. Does the result of the assay reflect the true value of the analyte? This requires a "gold standard" reference to compare results.
- *Precision*. Is the assay reproducible? Replicate values are typically required to be within variability.

Biomarkers have three additional characteristics[20,21]:

- *Sensitivity*. Does the assay discriminate between two states (e.g., the presence or absence of RA)?[22]
- *Specificity*. Does the assay discriminate between only the two states and avoid false positives (e.g., diagnosis of RA in a patient with systemic lupus erythematosus [SLE]).[23]
- *Stability*. Are the analyte and assays stable during the period and conditions of collection and measurement? In other words, will repeating the assay multiple times during a period of weeks or months provide the same results?[24]

## Biomarker Validation

Biomarker and assay validation is a complex process that includes (1) technical validation of the assay method and (2) validation of the application of the biomarker to answer or address a clinical question.[25,26] The basic parameters include a reference standard from which an assay working range and precision can be determined.[16] Sample processing is tuned to fit assay values within the assay's linear range, and acceptable precision is defined by the FDA at a coefficient of variation of 15% to 20%.[27] This establishes that an analyte can be measured, but not its utility.

Validation to address a specific clinical question (e.g., does it correlate with changes in disease activity or a clinical endpoint) requires multiple independent studies, consensus building, and perhaps meta-analysis to confirm the conclusions. This is particularly true for surrogate markers, which can replace a clinical endpoint for regulatory purposes.[28] For a biomarker to become a surrogate biomarker, it must meet substantially higher standards of technical validation and utility as a predictor of a traditional endpoint used for drug approval. In practice, few disease-specific surrogate markers have been developed to this level.[29]

A recent concept used to establish intermediate levels of validation applicable to biomarkers not meeting the surrogacy standard is "fit-for-purpose" analytic validation.[30] This approach includes validation of biomarker applications such as pharmacodynamic markers used for dosing and sensitive molecular measures correlated with clinical response used for decision making that are not approved surrogates. These "actionable" biomarkers can be used to stratify patients or monitor therapy and establish the companion diagnostics.

Some assays are discreet such as the presence or absence of a genetic mutation; many others are continuous measures

such as CRP level. However the marker is measured and reported, performance of a biomarker can be thought of in binary terms with respect to sensitivity and selectivity. Sensitivity measures true positive outcomes, whereas selectivity reflects the true negative result. The statistical model used to describe performance parameters of sensitivity and specificity is the receiver operating characteristic (ROC).[31] ROC space plots sensitivity versus specificity and can be thought of as graphical representation of the assay's propensity for type 1 (false positive) or type II (false negative) errors.[32] For example, CRP has good sensitivity for inflammation, but very poor specificity for rheumatic disease, whereas a marker such as anti–double-stranded DNA antibody might have good specificity for lupus, but poor sensitivity. The binary nature of the ROC illustrates that a biomarker is more than the measurement of an analyte. It must discriminate a biologic process, pathologic process, or response to therapy.

## Biomarker Timing

The timing of biomarker measurement is an important parameter in determining the value of the measurement. Although we often think of diurnal variations in serum or urine biomarkers, the utility of a biomarker might also vary during longer periods of time.[33] Different pathogenic processes may predominate at different times during the course of disease. On the other hand, similar final common pathways may drive late-stage diseases with varying initial disease mechanisms. For example, genetic and epigenetic markers in RA might be actionable early in the disease (or even before clinical manifestations), but disease activity markers could be more valuable after clinical signs develop. Biomarkers do not exist in a vacuum: CRP may be of limited value in detecting arthritis in a pre-clinical disease state, but in the context of established disease, it might associate closely with disease activity. Identifying markers that reflect a change in state, such as from early to established disease, could be valuable in selecting therapy or deciding when to start treatment.[34]

## Mechanistic and Descriptive Biomarkers

Actionable biomarkers are tests that could be used to guide the clinical management of disease.[35] For example, a diagnostic biomarker would meet this criterion when the knowledge of a disease diagnosis guides the initiation of a disease-modifying therapy. Mechanistic biomarkers, for which the biomarker is rooted in the biologic mechanisms of disease, provide the greatest potential for guiding clinical decision making.[35] A series of time points exist in the development and progression of RA and other autoimmune rheumatic diseases at which actionable biomarkers can be used to guide clinical decision making, including the presence of rheumatoid factors or anti-citrullinated protein antibodies (ACPA). Mechanistic biomarkers provide the potential to be superior other types of biomarkers.[36]

Descriptive biomarkers include erythrocyte sedimentation rate (ESR) and CRP, and reflect the state of a disease but are not directly involved in disease pathogenesis. For example, ESR and CRP are components of the RA disease activity score (DAS),[37] but these clinical laboratory biomarkers are not specific to RA and are elevated in many infectious and inflammatory diseases. Because descriptive biomarkers do not directly mediate disease pathogenesis, the value of the diagnostic and prognostic information they provide is limited.[35]

Mechanistic biomarkers can provide important advantages compared with descriptive biomarkers. Because the former are directly involved in disease pathogenesis, they are more likely to be disease specific. Further, they offer greater potential to provide utility as predictive and PD biomarkers because they represent the dysregulation of molecular pathways directly involved in pathogenesis.

## Biologic Sample Sources for Biomarker Assays

A variety of biologic samples can be utilized in molecular biomarker assays. The most accessible biologic samples include samples that can be obtained via noninvasive or minimally invasive acquisition and include urine, saliva, and peripheral blood.[38] However, the urine and saliva are likely to be limited to certain omics analyses (e.g., proteomics) and the measurement of certain joint and cartilage breakdown products in urine as biomarkers for osteoarthritis (OA).[39] Based on its accessibility, blood is widely used as a biologic sample for biomarker analysis. Although blood frequently contains the immune cells and molecules involved in rheumatic disease pathogenesis, it is usually not the tissue directly involved in rheumatic diseases. Therefore it does not always provide clear correlation to the dysregulated molecular pathways and molecules involved. Many groups are measuring molecular biomarkers in synovial tissue derived from RA, OA, and other rheumatic diseases. Although synovium provides the greatest access to mechanistic biomarkers that provide insight into the disease pathogenesis and therapeutic mechanism of action, it can be difficult to obtain, and analysis can be complicated by sampling error and the large number of cell lineages within the tissue.[40]

Although the collection of joint tissue has been limited by practical reasons to small clinical proof-of-concept trials, it requires consideration of an additional dimension of biomarker validation.[41,42] Synovium is a complex tissue with multiple functions in health and disease.[43] When inflamed, synovitis can be quite variable in terms of location within the joint as well as between different involved joints. To measure synovial biomarkers, a representative needs to be collected. Biopsies of synovial tissue for biomarker analysis require a minimum of six tissue fragments to minimize intrapatient variation.[44]

Synovial biopsy studies have yielded insights into the disease process and therapeutic mechanisms. One application is identifying soluble factors produced in the joint that can be detected in blood. Recently, synovial biopsies have yielded information on possible patient stratification based on histologic patterns and have been proposed as a source of clinical biomarkers.[6,45,46] When the joint is used as a source of biomarker material, synovial fluid is often considered because of its proximity to joint tissue and ease of collection.[47] However, synovial fluid volume itself is a poor biomarker, and the variability of synovial tissue renders it an unreliable source of biomarkers in many clinical circumstances.

### Biomarker Discovery

Assay systems that measure large numbers of analytes such proteins or metabolites are in theory a rich source of biomarker discovery. National and international efforts that use high-content genetic, epigenetic, and proteomic methods are in use to discover biomarkers in rheumatic diseases. Costs of "omics" assys are decreasing, and informatics methods are improving.[48] Nevertheless, challenges remain regarding how we apply these approaches to complex diseases, and the statistical hurdles are daunting because of the need for corrections for multiple comparisons. These methods are usually best thought of as hypothesis generating, and the analyte(s) selected require subsequent rigorous validation.[49] As such, study size and statistical threshold compromises are appropriate, and any candidate biomarker would require further study in a separate single-analyte assay. Single-measure tests, whether derived inductively from omics assays, or deductively from disease process or pharmacology, require formal validation in multiple independent cohorts.

The source of clinical material for biomarker discovery constrains the type of biomarkers evaluated. Peripheral blood is the most common material for biomarker studies, although rheumatic diseases are often not blood diseases. Any signature or marker present in blood can be either derived from or a response to conditions at the site of disease.[50] The use of joint tissues in arthritis studies is challenging, but it increases the possible markers to include intra-cellular and tissue-specific factors or mediators enriched in the local environment. An inclusive strategy is to start at the site of disease and then identify feasible methods of assay. Ideally, a blood assay detecting the marker directly or its surrogate could be developed. If not, an actionable biomarker might justify performing a synovial or other solid tissue biopsy to provide decision-making clinical material.[51]

### Biomarker Profiles

An alternative approach to biomarker discovery between the unbiased omics assays and the single-analyte assay is the creation of multiplexed panels of analytes. Narrowing the candidates limits the possibilities, but can be both practical and feasible. Many studies measuring blood plasma inflammatory mediators, such as cytokines, chemokines, and growth factors, have been performed without yielding a validated biomarker that is sensitive and specific.[52] However, the approach of using relatively small panels of candidate biomarkers has intrinsic statistical advantages, allowing for the panel itself to be consider a composite biomarker.[53] The performance of individual analytes can be modeled and its performance given a statistical weight within the panel.[54] Some markers receive increased weight; some may receive "0" weight and are removed.[55] Negative weights can also be used. The resulting multiplex assay can be performed in automated assays with good technical quality. One critical component often ignored is the fact that biomarkers in a panel should be independent and not part of a clinical disease assessment score. For example, many analytes, such as CRP and serum amyloid A protein, are regulated by interleukin (IL)-6. Thus any process that decreases IL-6 would decrease the others in a dependent fashion and only serves to amplify the effect of decreasing IL-6 in a composite biomarker assay. Similarly, if change is used to show correlation with the disease activity score (DAS), then interpretation becomes difficult because CRP is included in both the clinical and the biomarker analysis.

In many rheumatic diseases, profiles or panels of biomarkers could provide increased accuracy and utility in guiding diagnosis and therapeutic decision making. In rheumatic diseases, individual biomarkers are frequently associated with diagnosis or disease state at the population level, but might not exhibit sufficient predictive utility to be used at the level of the individual patient. The development of technologies that enable multiplex measurement of candidate biomarkers has greatly facilitated identification of biomarker profiles with increased diagnostic and predictive utility.[56,57] In the future, it will likely be possible to develop candidate panels from higher content unbiased methods.

## APPLICATION OF BIOMARKERS IN CLINICAL PRACTICE AND DRUG DEVELOPMENT

### Diagnosis of Established Disease

A frequent use of an actionable biomarker is diagnosing symptomatic established disease, and thereby establishing the basis for therapeutic intervention. For example, detection of autoantibodies, including rheumatoid factor and ACPA, contribute to the diagnosis of RA; detection of anti-nuclear antibodies (ANA) contribute to the diagnosis of SLE, and detection of anti-neutrophil cytoplasmic antibodies (ANCA) contribute to the diagnosis of ANCA-associated vasculitis. These autoantibodies could contribute to disease pathogenesis[58-61] and thus might be classified as actionable mechanistic biomarkers.

#### Diagnosis of Pre-clinical or Asymptomatic Disease

An important application of biomarkers is to identify individuals with pre-clinical disease. The ability to identify individuals before clinical onset of disease provides an opportunity for therapeutic intervention to prevent the development of symptomatic disease or to reduce the severity of symptomatic disease.[62,63] For example, profiles of specific subsets of ANA are detected in the blood of individuals who ultimately progress to have clinical SLE,[62] and this biomarker could potentially enable treatment to prevent development of SLE. In RA, profiles of autoantibodies and cytokines in blood can be used to identify asymptomatic individuals who will progress to have RA.[56,57,64] Therapeutic intervention in pre-clinical RA patients provides the potential to reduce the incidence or severity of RA in these individuals.[65]

#### Assessment of Disease Activity and Prognosis

Biomarkers that assess disease activity can identify patients with increased likelihood for progression, thereby guiding clinicians to institute a more aggressive therapeutic regimen. Such biomarkers are particularly valuable in diseases, and in individual patients, in which there is discordance between symptoms and disease activity, and can be used to guide selection of an appropriate therapeutic regimen.[66]

Although many biomarkers are imperfect, diseases activity and prognostic biomarkers include the ESR, CRP, complement proteins C3 and C4, and anti-DNA antibodies. Nevertheless, the sensitivity, specificity, and utility of these biomarkers are limited. In recent years a profile of inflammatory cytokines and molecules has been developed to assess disease activity in RA.[67,68] Nevertheless, it remains unclear whether this profile provides increased utility compared with the well-established DAS-28[37] or whether the profile is specific for RA (relative to other autoimmune, inflammatory, and infectious conditions).

## Pharmacodynamic Biomarkers

### Assessing Response to Therapy

PD biomarkers are tests that can be used to monitor response to therapy. PD biomarkers can be mechanistic or descriptive. Mechanistic PD biomarkers are directly related to the biological mechanism underlying the disease process, and this biologic mechanism can also be the target of the therapeutic intervention.[35] Descriptive PD biomarkers frequently represent generic inflammatory or tissue injury biomarkers, and such markers can be used to assess response to therapy but are not directly related to the biologic mechanism(s) of disease.

Examples of mechanistic PD biomarkers used in clinical practice in rheumatology are peripheral B cell and peripheral blood plasmablast analysis following rituximab therapy in patients with RA.[68,69] Flow cytometry is cumbersome and not readily amenable to widespread clinical use, and a PCR assay to measure IgJ transcripts, a marker for antibody-secreting plasmablasts, has been developed as a biomarker to guide clinical decision making.[70] In samples derived from trials of rituximab in inadequate responders to anti-TNF, 25% of treated subjects with elevated baseline mRNA levels of IgJ showed reduced clinical response rates.[70]

Examples of descriptive PD biomarkers used in clinical practice in rheumatology include ESR in polymyalgia and a rheumatic and inflammatory molecule panel reflective of disease activity in RA.[67] In SLE, quantification of proteinuria and analysis of urine sediment can be used to assess response to therapy.[71] Imaging technologies such as MRI[72] and ultrasound,[73] that enable assessment of synovitis in RA and other inflammatory arthritides, represent another biomarker of disease activity.

PD biomarkers play a central role in facilitating therapeutic development, particularly for demonstrating clinical proof-of-concept and assessing toxicity in early stages of drug development. They are prioritized by the FDA's Critical Path Initiative and described as having the potential to substitute for a clinical endpoint that "reflects how a patient feels, functions, or survives."[74-76] PD biomarkers can streamline clinical development and reduce costs by enabling rapid demonstration that a candidate therapeutic modulates pathogenic mechanisms. Although PD biomarkers are used to accelerate and reduce the costs of drug development, clinical endpoints still form the basis of regulatory approval by the FDA and other agencies.

PD biomarkers have been utilized to characterize the response to candidate therapeutics for autoimmune rheumatic diseases for decades. For example, in the 1990s it was demonstrated that decreases in blood levels of IL-1 are associated with clinical responses to methotrexate,[77] and that reductions in blood levels of CRP are associated with response to treatment with infliximab.[78]

Transcription profiles in peripheral blood cells are emerging as a potential biomarker in RA and other rheumatic diseases.[18] For example, reports suggest that peripheral blood RNA transcript profiles can predict the response of patients with RA to rituximab[18] and anti-TNF therapies.[79] Although the correlations are statistically significant, they are not robust enough to be useful for clinical decision making. Further, transcriptional profiling of genes associated with the type I interferon (IFN) pathway in samples derived from blood or skin have provided promising results for monitoring response to therapy in SLE[80] and scleroderma.[81]

Molecular biomarker studies extend to the primary site of disease pathogenesis in RA, the synovium. Decreases in the number of macrophages in the synovial sublining represent a potentially sensitive and early biomarker of therapeutic efficacy in RA, although responses to rituximab, abatacept, and tofacitinib are independent of this biomarker and therefore limit its utility.[82] Analysis of the activated states of the signal transduction molecules signal transducer and activator of transcription (STAT)1 and STAT3 in the synovial lining were demonstrated to correlate with clinical response to tofacitinib in RA (Figure 34-1).[83] The transcription profiles in RA synovium and other tissues involved in rheumatic diseases have also provided PD markers. In systemic sclerosis, transcriptional profiles in skin biopsies identified individuals with cutaneous sclerosis driven by the tyrosine kinases platelet-derived growth factor receptor (PDGF) and Abl, and are therefore predicted to be more likely to respond to treatment with receptor tyrosine kinase inhibitors.[84] In RA, gene expression analysis revealed synovial phenotypes that correlated with distinct responses to rituximab[85] and anti-TNF[86] therapy.

### Assessing Toxicity

PD biomarkers can potentially streamline drug development by enabling early detection of drug-related toxicity, a significant source of the failure of novel investigational drugs in human trials.[87] Examples of PD toxicity biomarkers include clinical laboratory variables, such as liver function and renal function tests, as well as biomarkers of cardiac toxicity, such as prolongation of the QT interval on electrocardiogram, increased blood pressure, and alterations in lipid profiles. Moving forward, identification of new biomarkers that serve as more reliable indicators of organ or tissue toxicity will further accelerate the development of novel therapeutics for RA and other rheumatic diseases.

## Predictive Biomarkers

Predictive biomarkers predict response to therapy before the therapy is initiated. A key challenge in both clinical practice and drug development is selection of the subset of patients in whom the mechanism that the drug targets is active.[88] The ability to identify responders in advance of treatment provides significant benefits to patients, both in the reduction of health care costs and in the acceleration of clinical development of next-generation therapeutics.[89]

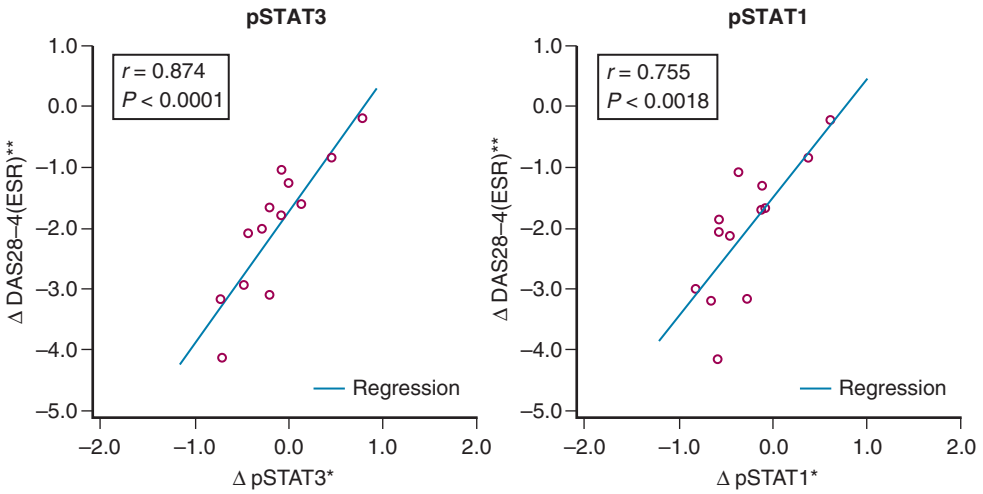

**Figure 34-1** Tofacitinib-induced synovial changes in pSTAT3 and pSTAT1 predict clinical response at month four**.** pSTAT1 and pSTAT3 were measured in serial synovial biopsies obtained from tofacitinib-treated patients with rheumatoid arthritis, and the graphs demonstrate that the changes in pSTAT1 and pSTAT3 correlated with clinical response. *Biomarker data change from baseline (day 7) to day 28; **disease activity scale (DAS)28-4 (erythrocyte sedimentation rate) change from day 1 to month 4. pSTAT, phosphorylated signal transducer and activator of transcription; *r*, correlation coefficient. *(From Boyle DL, Soma K, Hodge J, et al: The JAK inhibitor tofacitinib suppresses synovial JAK1-STAT signalling in rheumatoid arthritis.* Ann Rheum Dis *74:1311–1116, 2015.)*

In oncology, predictive single-gene biomarkers are routinely used in both clinical practice and drug development. For example, in breast cancer, overexpression of *HER2* indicates responsiveness to anti-Her antibody (trastuzumab, pertuzumab), and in chronic myelocytic leukemia, the *BCR-ABL1* translocation is indicative of responsiveness to imatinib. In contrast, RA and other rheumatic diseases are not driven by single-gene mutations, and both single-gene biomarkers and multiple-gene biomarkers have not provided significant predictive utility to date.[90] Ongoing work is investigating epigenetic biomarkers in RA, and such epigenetic biomarkers hold great potential.[91]

Drug developers and the FDA recognize the opportunity and power of predictive biomarkers, and the FDA has undertaken initiatives to facilitate the development of predictive and PD biomarkers for candidate therapeutics.[74-76] The cost of therapeutic development has skyrocketed in the past decades,[92] and integrated use of predictive and pharmacodynamic biomarkers represents an important strategy to streamline clinical development and thereby reduce the cost of development of next-generation therapeutics.[35]

## Mechanistic Biomarkers

### Cytokines

Rheumatic disease diagnoses, such as SLE and RA, often comprise multiple disease subtypes that may exhibit similar clinical presentations but differ markedly in molecular phenotype. Insight into the pathogenesis of disease provides the basis for developing mechanistic biomarkers to distinguish these molecular subtypes of disease, and thereby guide selection of the most appropriate therapy for each patient. Although targeting TNF, IL-6, IL-1, and other cytokines has provided benefit in some patients with RA and subsets of patients with other autoimmune rheumatic diseases, to date simple measurement of the corresponding cytokine levels in blood, synovial tissue, or synovial fluid has failed to yield predictive biomarkers for therapeutic response.[93]

For RA, a potential cytokine biomarker is CXCL13, also known as B lymphocyte chemoattractant. CXCL13 plays a key role in germinal center formation, and increased levels of CXCL13 mRNA in RA synovium is associated with synovial germinal centers and increased blood CXCL13.[94] In addition to B cells, osteoblasts express the CXCR5 receptor for CXCL13. CXCL13 stimulates osteoblasts to release degradative enzymes,[95] and CXCL13 has been identified as a potential biomarker of erosive progression.[96] Blood levels of CXCL13 decreased with response to anti-TNF therapy. A human anti-CXCL13 monoclonal antibody has been developed and is under evaluation. Further studies will be needed to further determine the sensitivity, specificity, and predictive utility of blood CXCL13 as a candidate mechanistic biomarker in RA. 14-3-3n, a soluble signaling molecule measurable in serum that is associated with joint damage in RA, has been proposed as a potential biomarker.[97]

A more advanced approach compared with simple measurement of blood or synovial fluid cytokines is being undertaken in the search for mechanistic biomarkers for SLE. SLE is associated with increased levels of type I IFNs in blood, and type I IFNs are believed to contribute to the pathogenesis of SLE.[98] Increased levels of type I IFN-induced mRNAs are associated with increased disease activity in SLE,[99] and profiles type I IFNs mRNAs are already used as disease activity biomarkers in clinical trials.[80] The type I IFN-induced transcriptional signature represents an actionable mechanistic biomarker for SLE.

### Autoantibodies

Autoantibodies exemplify mechanistic biomarkers for RA, SLE, and certain other autoimmune rheumatic diseases. In SLE, autoantibodies specific for RNA-, DNA- or chromatin-associated proteins result in the formation of immune complexes that dually stimulate dendritic cells via Toll-like receptors (TLRs) 7 or 9 to produce type I IFNs.[100,101] Such autoantibodies are associated with increased blood IFN-α activity, as assessed by in vitro induction of IFN-induced

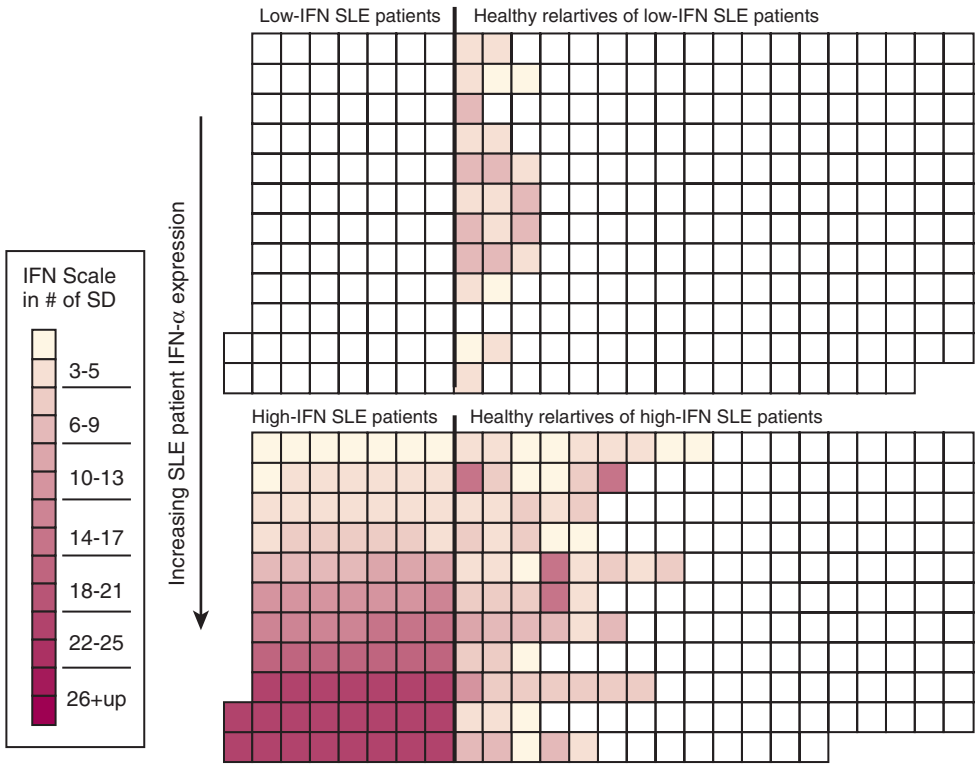

**Figure 34-2** Familial aggregation and correlation of interferon (IFN)-α activity in first-degree relatives of patients with systemic lupus erythematosus (SLE). Each box represents a person, with the *solid bold line* separating patients with SLE from healthy first-degree relatives. *White shading* indicates no significant difference from healthy unrelated donors, and *increasing yellow to red shading* indicates increasing quantitative IFN-α activity. SLE patients are ordered by quantitative IFN-α activity in ascending order, with the lowest at top left, the highest at bottom right. The gap in the middle of the diagram represents the categorical cutoff for high versus low IFN activity in the SLE patients. Healthy relatives are then arrayed on the right side of the bold line, ordered by the IFN-α activity value of their corresponding SLE-affected family to show the variance in familial IFN-α activity as it relates to the SLE affected in the same family. Boxes representing family members with high IFN-α activity are moved centrally within the same row to allow easier comparison of the relative proportion of high IFN-α family members between rows. *(From Niewold TB, Hua J, Lehman TJ, et al: High serum IFN-alpha activity is a heritable risk factor for systemic lupus erythematosus.* Genes Immun *8:492–502, 2007.)*

gene expression (Figure 34-2).[102] RNA-, DNA- and chromatin-associated autoantigens can also dually stimulate autoreactive B cells via membrane Ig and TLR7 or TLR9 to produce autoantibodies.[101]

In RA, ACPA binds citrullinated fibrinogen, vimentin, histones, and multiple other citrullinated antigens.[103,104] Citrullinated fibrinogen binds TLR4 to stimulate macrophage to produce TNF, and citrullinated fibrinogen immune complexes synergistically stimulate macrophages to produce TNF via co-ligation of TLR4 and Fcγ receptors.[60] Thus, in both SLE and RA autoantibodies, the binding of immunologically active autoantigens (such as RNA, DNA chromatin, or citrullinated fibrinogen) drive the activation of inflammatory pathways that contribute to disease pathogenesis. As a result, these autoantibodies represent mechanistic biomarkers.

Autoantibody profiling has been demonstrated to provide utility for early diagnosis and for identifying at-risk individuals likely to progress to SLE or RA. Autoantibodies are present in the blood for years before clinical SLE[62] or RA develops.[105,106] Similarly, increased levels of cytokines[57] and other inflammatory markers[105] are also present in the blood before the onset of clinical RA. Further, epitope spreading and the accumulation of multiple antibody specificities precede the onset of clinical symptomatic RA.[63,103]

For RA, detection of autoantibodies in at-risk individuals or in early-stage disease might also be used to guide treatment. For example, in individuals with undifferentiated arthritis, methotrexate treatment reduced the rate of progression to clinical RA, but this effect was only found in in ACPA$^+$ individuals.[107] Thus, in individuals with undifferentiated arthritis, ACPA represents a potential mechanistic biomarker that could be used to guide therapeutic intervention. In another dimension, in the future detection of autoantibodies targeting immunologically active antigens has the potential to enable section of a therapeutic specific for the relevant downstream inflammatory pathway (e.g., therapies that target Janus kinases, spleen tyrosine kinase, IL-6, TNF, IL-1, and IL-17).

## Epigenetic Biomarkers

Epigenetic markers represent an emerging class of mechanistic biomarkers. Epigenetic regulators include DNA methylation, histone modification, and microRNAs (miRNAs), and each contributes to pathogenic mechanisms in autoimmunity.[91] For example, in RA fibroblast-like synoviocytes (FLS), alterations of imprinted DNA methylation have been identified even in very early RA that can modulate cell migration, matrix regulation, and immune responses.[108]

miRNAs are another subclass of epigenetic factors that regulate rheumatic diseases.[109] An individual miRNA regulates the mRNA stability and translation of multiple genes,

and thus exert broad biologic effects. miR-146a is expressed by activated T cells in which it suppresses apoptosis and IL-2 production,[110] miR-146a is expressed in RA synovium, and synovial expression is associated with increased disease activity. Another candidate miRNA biomarker is miR-155, which induces development of Th1 cells and Th17 cells,[111] and increased expression is observed in peripheral blood mononuclear cells from patients with RA. These observations suggest that miRNAs might prove to be mechanistic biomarkers. Further studies are needed to rigorously assess the predictive value, reproducibility of detection, and utility of miRNAs as biomarkers of RA and other rheumatic diseases.

### Metabolomics

Metabolomics is an emerging area of investigation.[112] Alterations in T cell metabolism have been associated with RA,[113] and future studies will determine whether these alterations provide utility as mechanistic biomarkers. Alterations in RA FLS choline metabolism have also been identified, which could serve as clues to how metabolic enzymes could be targeted in rheumatic disease.[114] Studies characterizing a spectrum of metabolites in RA and other rheumatic diseases are ongoing, and it remains to be determined if any of these will have utility as actionable and/or mechanistic biomarkers.

## Tissue Degradation Product Biomarkers

Joint, cartilage, and other tissue degradation products represent another class of biomarkers. Although cartilage breakdown products are classically used to monitor tissue injury in OA or RA,[115] more recently cartilage and tissue breakdown products have been demonstrated to function as damage-associated molecular patterns (DAMPs)[116] that possess innate immune stimulatory activity, tissue-repair–promoting activity, or both. For example, syndecans are proteoglycans released during joint tissue injury that promote cartilage development and remodeling.[117] In contrast, tenascin-C is a cartilage protein released in RA and OA that binds TLR4 to stimulate innate immune-mediated inflammation.[118] In another example, the cartilage matrix protein fibromodulin has been demonstrated to activate the complement system to produce the membrane attack complex and thereby contribute to the pathogenesis of OA.[119] Urinary measures of α-C-telopeptide of type I collagen (α-CTX) and C-telopeptide of type II collagen (CTX-II) reflect bone turnover and osteophyte activity (Figure 34-3).[120] Thus cartilage and tissue degradation products represent

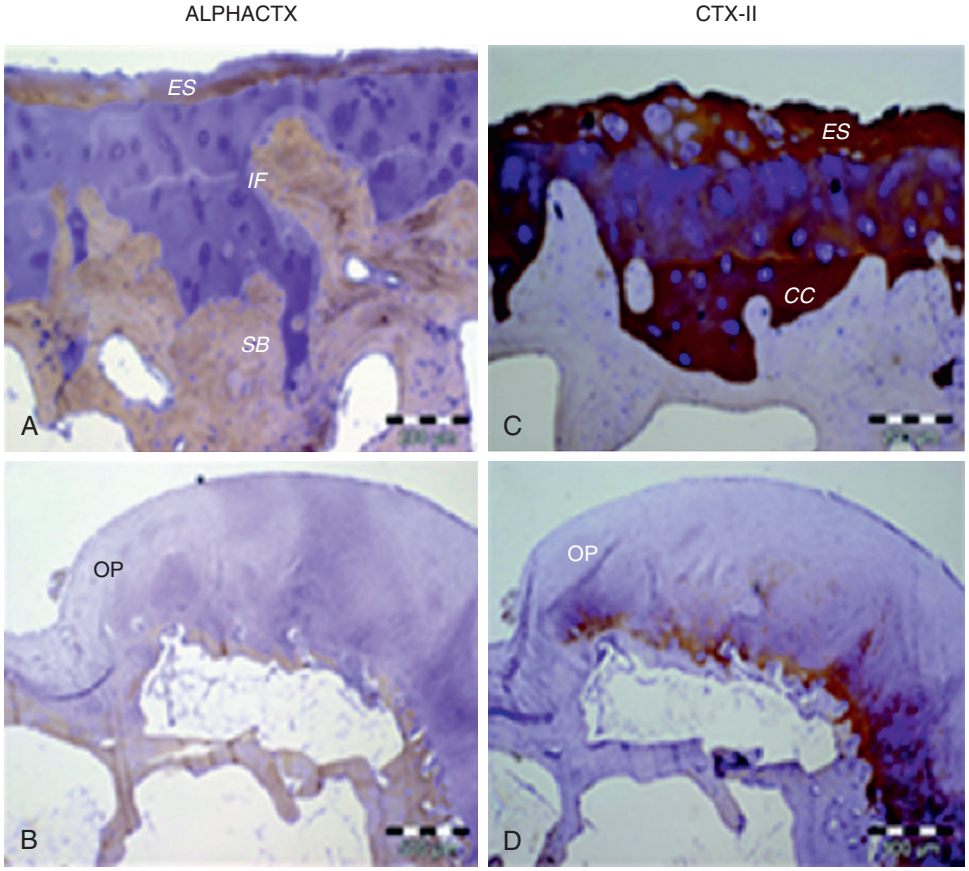

**Figure 34-3** Biomarkers of cartilage and bone damage can correlate with tissue damage. Immunolocalization of α-C-telopeptide of type I collagen (α-CTX) and C-telopeptide of type II collagen *(CTX-II)* in human osteoarthritis cartilage and bone from patients with severe erosions of the cartilage. **A** and **C**, Staining for α-CTX (**A**) and CTX-II (**C**) in sections from a severely eroded area with an eroded surface (ES), thickening of the subchondral bone (SB), and bone invasion fronts (IF) through the calcified cartilage (CC). **B** and **D**, Staining for α-CTX (**B**) and CTX-II (**D**) in sections from an area from the rim of the cartilage where an osteophyte (OP) is forming (i.e., chondrophyte), seen by the diffuse structure of the tissue. No background immunostaining was observed with the immunoglobulin G control (results not shown). Bars = 200 μm in **A** and **C**; 500 μm in **B** and **D**. IFN, Interferon; SLE, systemic lupus sclerosis. *(From Huebner JL, Bay-Jensen AC, Huffman KM, et al: Alpha C-telopeptide of type I collagen is associated with subchondral bone turnover and predicts progression of joint space narrowing and osteophytes in osteoarthritis.* Arthritis Rheumatol *66:2440–2449, 2014.)*

potential mechanistic biomarkers in RA and OA. Furthermore, they have potential to provide early information on the effect of novel therapeutic agents on tissue damage.

## CONCLUSION

Expectations that biomarkers can be used to diagnose and stratify rheumatic diseases must be tempered by evidence that there are no simple answers and no single analyte that will suffice. Complex diseases might require an integrative approach that includes multiple technology platforms and careful assessment of unbiased platforms. Surrogate biomarker discovery remains even more elusive. On the other hand, new standards for biomarker validation have been established and provide application-specific validation methods. Understanding the role and context of a proposed biomarker is critical. Single-analyte biomarkers have increased use in mechanistic studies and as companion diagnostics. Panels of analytes or omics-derived markers could be more sensitive measures of disease activity. The identification and use of fit-for-purpose markers to stratify patients for targeted therapy is a realistic goal.

CHAPTER 35

# Occupational and Recreational Musculoskeletal Disorders

Richard S. Panush

## KEY POINTS

- Some occupational and recreational activities have been linked with musculoskeletal syndromes or disorders that are manifested by neck pain; shoulder, elbow, hand, or wrist pain or tendinitis; carpal tunnel syndrome; and hand-arm vibration syndrome. These associations might be less clear than has been previously thought.
- The intuitive concepts of so-called cumulative trauma disorders and repetitive strain disorders have poor support in the literature. Causal relationships between most occupations or activities and these "syndromes" have not been well established.
- Some activities and mechanical stresses have been associated with osteoarthritis at certain sites—for example, the hips of farmers, the knees of workers whose jobs involved frequent bending of the knees, and the hands of workers who perform repetitive tasks with their hands.
- Certain rheumatic disorders have been related to environmental or occupational risks.
- Putting a normal joint through its physiologic range of motion is not necessarily harmful for an otherwise healthy individual. However, if the joint, motion, stress, or biomechanics are not normal, there may be a risk of harm to the joint.
- Most healthy persons comfortably engaging in reasonable recreational activities can do so without evidence of lasting soft tissue or articular damage. Runners, who have been best studied, exemplify this principle. Conversely, persons who exercise with pain, effusions, underlying joint abnormalities or abnormal or unusual biomechanics, or as professional or elite athletes may be at increased risk of joint injury.
- Performing artists, vocalists, dancers, and musicians have a risk of soft tissue and joint injury analogous to that of athletes.

**"The diseases of persons incident to this craft arise from three causes: first constant sitting, second the perpetual motion of the hand in the same manner, and thirdly the attention and application of the mind. … Constant writing also considerably fatigues the hand and whole arm…."**

—Ramazzini, 1713[1]

**"When job demands … repeatedly exceed the biomechanical capacity of the worker, the activities become trauma-inducing. Hence, traumatogens are workplace sources of biomechanical strain that contribute to the onset of injuries affecting the musculoskeletal system."**

—National Institute for Occupational Safety and Health, 1986[2]

The possible associations of certain occupational and recreational activities with musculoskeletal disorders are not as clear as had once been thought. Conventional wisdom was that "wear and tear" from at least some activities led to reversible or irreversible damage to the musculoskeletal system.[2-5] Despite the intuition that work or recreational activities might cause rheumatic and musculoskeletal syndromes, this putative relationship is controversial and likely seriously flawed. Many of the available data have confounding aspects, as will be discussed in this chapter.

## OCCUPATION-RELATED MUSCULOSKELETAL DISORDERS

Many presumptive work-related musculoskeletal disorders have been described and are presented in Table 35-1.[1-8] Although the appealing and suggestive names invite conclusions of causal association, these have not been demonstrated.[1-8] Work-related musculoskeletal injuries comprise at least 50% of nonfatal injury cases resulting in days away from work.[9] The cost of work-related disability from musculoskeletal disorders has been equivalent to approximately 1% of the United States' gross national product, making these entities of considerable societal interest.[10] Worldwide ergonomic (occupational) disability from low back pain in 2010 was estimated to affect as much as 26% of the population.[11] Industries with the highest rates of musculoskeletal disorders were meatpacking, knit-underwear manufacturing, motor vehicle manufacturing, poultry processing, mail and message distribution, health assessment and treatment, construction, butchery, food processing, machine operation, dental hygiene and dentistry, data entry, hand grinding and polishing, carpentry, industrial truck and tractor operation, nursing assistance, housecleaning, and, worldwide, agriculture. Associations between work-related musculoskeletal syndromes and age, gender, fitness, and weight have been imprecise.[6-8,11]

A number of work-related regional musculoskeletal syndromes have been described. These syndromes include disorders of the neck, shoulder, elbow, hand and wrist, lower back, and lower extremities[7] (Table 35-2); some of these syndromes are discussed in greater detail in other chapters. Neck musculoskeletal disorders are associated

**TABLE 35-2** Selected Literature Describing Regional Occupation-Related Musculoskeletal Syndromes

| Syndrome | No. of Epidemiologic Studies | Odds Ratio/ Relative Risk |
|---|---|---|
| Neck pain | 26 | 0.7-6.9 |
| Shoulder tendinitis | 22 | 0.9-13 |
| Elbow tendinitis | 14 | 0.7-5.5 |
| Hand-wrist tendinitis | 16 | 0.6-31.7 |
| Carpal tunnel syndrome | 22 | 1-34 |
| Hand-arm vibration syndrome | 8 | 0.5-41 |

with repetition, forceful exertion, and constrained or static postures. Shoulder musculoskeletal disorders occur with work at or above shoulder height, lifting of heavy loads, static postures, hand-arm vibration, and repetitive motion. For elbow epicondylitis, risk factors are overexertion of finger and wrist extensors with the elbow in extension, as well as posture. Hand-wrist tendinitis and work-related carpal tunnel syndrome were noted with repetitive work, forceful activities, flexed wrists, and duration of continual effort.[1,7] Hand-arm vibration syndrome (Raynaud-like phenomenon)[12] has been linked to the intensity and duration of exposure to vibration. Work-related lower back disorders are associated with repetition, the weight of objects lifted, twisting, poor biomechanics of lifting, and particularly agriculture.[11,13] Other risk factors for work-related musculoskeletal disorders involving the back include awkward posture, high static muscle load, high-force exertion at the hands and wrists, sudden applications of force, work with short cycle times, little task variety, frequent tight deadlines, inadequate rest or recovery periods, high cognitive demands, little control over work, a cold work environment, localized mechanical stresses to tissues, and poor spinal support.[1]

Rehabilitation for these so-called occupational musculoskeletal disorders requires collaboration by workers, employers, insurers, and health professionals. The process has been divided into phases of protection from and resolution of symptoms, restoration of strength and dynamic stability, and return to work.

Not long ago, the prevailing view was that many musculoskeletal disorders were consistently and predictably work related. That understanding has been questioned and is now perceived more critically.[2,14-20] Much published information (see Table 35-2) about occupational musculoskeletal disorders is now considered flawed. The quality of this information was uneven and perhaps poor in some instances. Definitions of musculoskeletal disorders were imprecise. Diagnoses, by rheumatologic standards, were infrequent. Studies were usually not prospective, and selection and recall biases were present. Inferential observations were made, and investigators had difficulty quantifying activities and defining health effects. Outcome measures varied. The quality of reported observations was uneven. Psychologic influences and secondary gain were often ignored. Claims, anecdotal, and survey data were often used without validation of subjective complaints. Quantification of putative causative factors was difficult. Indeed, a review of this literature concluded that none of the published studies satisfactorily established a causal relationship between work and distinct medical entities.[17] In fact, certain experiences argued powerfully against the notion of work-related musculoskeletal disorders. In Lithuania, for example, where insurance was limited and disability was not a societal expectation or entitlement, "whiplash" from auto accidents did not exist.[16] Similarly, when legislation for compensability was made more stringent in Australia, an epidemic of whiplash and repetitive-strain injuries abated.[18,19] In the United States as well, expressed symptoms correlated closely with the likelihood of obtaining compensation.[21] In other instances it was found that ergonomic interventions had no effect on alleged work-related symptoms, and close analysis of epidemics of work-related musculoskeletal disorders revealed serious inconsistencies.[14] A Japanese study found no relationship between physical activity and musculoskeletal pain.[22] Interestingly, another report described familial linkage to chronic musculoskeletal pain.[23] Thus the Industrial Injuries Committee of the American Society for Surgery of the Hand and the American Society for Surgery of the Hand, the Working Group of the British Orthopaedic Association, and the World Health Organization[2,14,17,18] have all stated that current data do not support a causal relationship between specific work activities and the development of well-recognized disease entities; in addition, they have noted that these had become socio-political problems and urged restraint in considering regulations regarding these so-called entities.[15] Hadler[2,14] also has written particularly forcefully that popular notions about work-related musculoskeletal disorders have been based on inadequate science.

An appreciation of the importance of psychosocial factors influencing work disability has emerged. These factors include lack of job control, fear of layoff, monotony, job dissatisfaction, unsatisfactory performance appraisals, distress and unhappiness with co-workers or supervisors, repetitive tasks, duration of the work day, poor quality of

sleep, perceptions of air quality and ergonomics, poor coping abilities, divorce, low income, less education, poor social support, presence of chronic disease, self-rated perception of poor air quality, and poor office ergonomics.[2,14-21,24,25] This situation is reminiscent of the story of silicone breast implants and their presumed association with rheumatic disease, where—as seems to be the case for work-related musculoskeletal disorders—there was a coalescence of naïvely simplistic assumptions, untested hypotheses, confusion between the repetition of hypotheses and their scientific validation, media exaggeration, and public advocacy intertwined with politics and governmental regulatory agencies, confounding compensatory rewards, litigation, and inadequate science. All these elements perverted the silicone breast implant story[26] and may have confused the interpretation of evidence-based work-related musculoskeletal disorders as well. More good quality, standardized investigation is necessary to learn about work-related musculoskeletal disorders and to clearly identify the circumstances in which they occur. Work-related musculoskeletal disorders exist, but they are less pervasive and less noxious than originally thought.

## OCCUPATION-RELATED RHEUMATIC DISEASES

Associations between occupations and well-defined rheumatic disorders are clearer than those involving musculoskeletal disorders. This discussion also recapitulates the simplistic perception that joints deteriorate with use. However, this notion is neither necessarily logical nor correct.

### Osteoarthritis

Is osteoarthritis (OA) caused, at least in part, by mechanical stress? OA is presented in Chapters 98 to 100; however, brief consideration of the role of certain occupational and recreational activities is within the scope of this discussion. One analytic approach to determining a possible relationship between activity and joint disease is to consider the epidemiologic evidence that degenerative arthritis may follow repetitive trauma. Most discussions of the pathogenesis of OA include a role for "stress."[27-40] Several studies have suggested an increased prevalence of OA of the elbows, knees, and spine in miners[31-33]; of the knees in floor layers and in other occupations requiring kneeling; of the knees in shipyard workers and a variety of occupations involving knee bending; of the shoulders, elbows, wrists, and metacarpophalangeal joints in pneumatic drill operators[34]; of the intervertebral disks, distal interphalangeal joints, elbows, and knees in dockworkers[32]; of the hands in cotton workers,[35] diamond cutters,[31,36] seamstresses,[36] and textile workers[14,37]; of the knees and hips in farmers; and of the spine in foundry workers[39,40] (Table 35-3). Population studies have noted increased hip OA in farmers, firefighters, mill workers, dockworkers, female mail carriers, unskilled manual laborers, fishermen, and miners and have reported increased knee OA in farmers, firefighters, construction workers, house and hotel cleaners, craftspeople, laborers, and service workers.[39,40] Activities leading to an increased risk for premature OA involved power gripping, carrying, lifting, increased physical loading, increased static loading, kneeling, walking, squatting, and bending.[39,40] Recent studies and systematic reviews have confirmed that heavy lifting and crawling and sometimes climbing were associated with knee and hip OA; individual studies were variable, often small, and with interpretive limitations.[41] The effect of body mass index (BMI) in work-related OA appeared to predispose toward the development of knee OA, with primarily valgus malalignment.[42,43] A recent systematic review and meta-analysis concluded that data supported risk of OA from activities involving heavy or manual work (average relative risk [RR], 1.45; range, 1.20 to 1.76), elite sports (RR, 1.72; range, 1.35 to 2.20), kneeling (RR, 1.30; range, 1.03 to 1.63), squatting (RR, 1.40; range, 1.21 to 1.61), lifting/carrying (RR, 1.58; range, 1.28 to 1.94), climbing stairs (RR, 1.29; range, 1.08 to 1.55), standing work (RR, 1.11; range, 0.81 to 1.51), and knee bending/straining (RR, 1.60; range, 1.15 to 2.21).[44] A common theme for occupational activities leading to knee OA was cumulative joint loading.[45] Bending was associated with magnetic resonance imaging abnormalities in cartilage of asymptomatic persons,[46] as was physical activity, assessed by objective measures[47-49]; injuries accelerated progression of knee OA.[50]

Studies of skeletons of several populations have suggested that age at onset, frequency, and location of osteoarthritic changes were directly related to the nature and degree of physical activities.[51] However, not all these studies adhered to contemporary standards, nor have they been confirmed. One report, for example, failed to find an increased incidence of OA in pneumatic drill users and criticized inadequate sample sizes, lack of statistical analyses, and omission of appropriate control populations in previous reports.[33] The investigators further commented that earlier work was "frequently misinterpreted" and that their studies suggested that "impact, without injury or preceding abnormality of either joint contour or ligaments, is unlikely to produce osteoarthritis."[34]

Do epidemiologic studies of OA implicate physical or mechanical factors related to disease predisposition or development? The first national Health and Nutrition Examination Survey of 1971 to 1975 (HANES I) and the Framingham studies explored cross-sectional associations between radiographic OA of the knee and possible risk factors.[38-43,52] Strong associations were noted between knee OA and obesity and occupations involving the stress of knee bending, but not all habitual physical activities and leisure-time physical activities (e.g., running, walking, team sports, racquet sports, and others) were linked with knee OA.[27-29,53-55] (See Chapter 98 for a more detailed discussion of the pathogenesis of OA.)

### Other Occupational Rheumatologic Disorders

Certain rheumatic diseases other than repetitive strain or cumulative trauma disorders have been reported to be associated with occupational risks. Reports have been made of reflex sympathetic dystrophy after trauma; Raynaud's phenomenon with vibration or exposure to chemicals (particularly polyvinyl chloride); autoimmune disease from teaching at a school, farming, occupations with exposure to animals and pesticides, mining, use of a textile machine, and decorating operations[40,56]; scleroderma from exposure to

**TABLE 35-3** Occupational Physical Activities and Possible Associations with Osteoarthritis

| Occupation | Involved Joints | Risk of OA | References |
|---|---|---|---|

chemicals, silica, and solvents and with use of vibrating tools[57,58]; scleroderma-like syndromes from exposure to rapeseed oil and L-tryptophan[58,59]; systemic lupus erythematosus from exposure to the sun, silica, mercury, pesticides, nail polish, paints, dye, canavanine, hydrazine, and solvents[60,61] and with shiftwork and patient contact[62]; lupus, scleroderma, and Paget's disease from exposure to pets[63]; granulomatous vasculitis from exposure to mercury and lead[64]; primary systemic vasculitis from farming, exposure to silica and solvents, and allergy[65]; anti-synthetase syndrome from exposure to dust, gas, and fumes[66]; arthritis in patients with psoriasis from infections requiring antibiotics and in persons who have performed heavy lifting[67]; spondyloarthropathy from stressful events[68]; gout (saturnine) and hyperuricemia with lead intoxication[69]; and rheumatoid arthritis (Caplan's syndrome) with silica exposure, farming, mining, quarrying, electrical work, construction and engine operation, nursing, religious, juridical, and other social science–related work, smoking, traffic and pollution, insecticides, and periodontal disease[70-72] (Table 35-4).

## RECREATION- AND SPORTS-RELATED MUSCULOSKELETAL DISORDERS

Do recreational or sports-related activities lead to musculoskeletal disorders?[72-98] It has been suggested that the risk of joint degeneration is increased by participation in sports that have high impact levels with torsional loading.[72] The presence of prior joint injury, surgery, arthritis, joint instability and/or malalignment, neuromuscular disturbances,

and muscle weakness also predispose to higher risks of joint damage during sports participation.[72] Persons with sports injuries to the anterior cruciate and medial collateral ligaments (such as from downhill skiing and football) frequently experienced the chondromalacia patellae and radiographic abnormalities of OA (20% to 52%).[27-29] Retrospective studies found that OA was associated with varus deformity, previous meniscectomy, and relative body weight.[73,74,99] Both partial and total meniscectomies have been linked with degenerative changes. Early joint stabilization and direct meniscus repair surgery may decrease the incidence of premature OA. Observations like these support the concept that abnormal biomechanical forces, either congenital or secondary to joint injury, are important factors in the development of exercise-related OA.[27-29] Other observations include certain physical characteristics of the participant, biomechanical and biochemical factors, age, gender, hormonal influences, nutrition, characteristics of the playing surface (when applicable), unique features of particular sports, and duration and intensity of exercise participation, as has been reviewed extensively elsewhere.[27-29] It is increasingly recognized that biomechanical factors have an important role in the pathogenesis of OA, as has been presented.

Is regular participation in physical activity associated with degenerative arthritis? Several animal studies (of tentative scientific relevance, but of interest) have suggested a possible relationship between exercise and OA. For example, it has been stated that the husky breed of dog has increased hip and shoulder arthritis associated with pulling sleds, that tigers and lions develop foreleg OA related to sprinting and running, and that racehorses and workhorses develop OA in the forelegs and hind legs, respectively, consistent with their physical stress patterns.[27,29] In rabbits with experimentally induced arthritis in one hind limb, progressive OA did not develop when they exercised on treadmills, but OA did develop in sheep with normal health who walked on concrete. Other studies found that OA did not develop in dogs (beagles) who ran 4 to 20 km a day,[27-29] that lifelong physical activity (running) protected mice from OA,[100] that running 30 km in 3 weeks or 55 km in 6 weeks induced OA in rats,[101] and that running exacerbated induced OA in other rats.[102] Although these observations were not entirely consistent, they suggested that physical activities in some circumstances might predispose to degenerative joint disease.

Human studies have provided pertinent observations[27-29] (Table 35-5). Wrestlers were reported to have an increased incidence of OA of the lumbar spine, cervical spine, and knees; boxers, of the carpometacarpal joints; parachutists, of knees, ankles, and spine, which was not confirmed; cyclists, of the patella; cricketers, of the fingers; and basketball and volleyball players, of the knees..[27-29,42] In addition, athletes involved in sports requiring repetitive overhead throwing such as baseball, tennis, volleyball, and swimming were reported to have an increased incidence of early glenohumeral arthritis[77]; persons with meniscal and anterior cruciate ligament injuries incurred in youth-related sports were reported to have an increased incidence of knee OA[78]; soccer players were reported to have an increased incidence of OA of the talar joint, ankle, cervical spine, knee, and hip[27-29,79-82,99]; and OA of the hips and knees of elite athletes from impact sports.[83] Studies of American football players have suggested that they are susceptible to OA of the knees, particularly those who sustained knee injuries while playing football.[30] Among football players (average age, 23 years) competing for a place on a professional team, 90% had radiographic abnormalities of the foot or ankle, compared with 4% of an age-matched control population; linemen had more changes than did ball carriers or linebackers, who in turn had more changes than did flankers or defensive backs. All athletes who had played football for 9 years or longer had abnormal radiographic findings.[27-30,78] Most of these studies were deficient in several respects: criteria for OA (or "osteoarthrosis," "degenerative joint disease," or "abnormality") were not always clear, specified, or consistent; duration of follow-up was often not indicated or was inadequate to determine the risk of musculoskeletal problems at a later age; intensity and duration of physical activity were variable and difficult to quantify; selection bias toward persons exercising or participating versus those not exercising or participating was not weighted; other possible risk factors and predispositions to musculoskeletal disorders were rarely considered; studies were not always properly controlled, and examinations were not always "blind"; little information regarding nonprofessional, recreational athletes was available; and little clinical information about functional status was provided.[27-29,75,76,99]

A number of studies have examined a possible relationship between running and OA. Uncontrolled observations generally suggested that runners without underlying biomechanical problems of the lower extremity joints did not

†This risk level is true of all of the sports listed except running.

develop arthritis at a different rate from a normal population of nonrunners. However, persons who had underlying articular biomechanical abnormalities from a previously injured joint (and perhaps elite athletes, particularly women) appeared to be at greater risk for the subsequent development of OA. Early studies showed that groups of long-duration, high-mileage runners and nonrunning control subjects had a comparable (and low) prevalence of OA and suggested that recreational running need not inevitably lead to OA.[103] These observations have generally now been confirmed by the original authors in long-term follow-up studies[85] and by other investigators[27-29,75,76,79,84-86,91,98,103] and in comprehensive reviews[88,99,104] (Table 35-6). Eight- and 9-year follow-up observations were supportive; most of

the original runners were still running, with a prevalence of OA that was comparable with that of the control subjects.[76] Perhaps even more significant was the growing evidence that running and other aerobic exercise protected against the development of disability and early mortality.[84] In another study,[85] former college varsity long-distance runners were compared with former college swimmers; no association was found between moderate levels of running or number of years running and the development of symptomatic OA. Other authors have concluded that running in and of itself does not cause OA; rather, prior injuries and anatomic variances were directly responsible for some of the changes.[27-29,103] Prospective studies have found that runners were not at risk for the development of premature OA of the knees.[85-90] Runners had hip replacements less frequently than did other persons (perhaps related to lower BMIs).[91] However, another recent study found that running 20 miles per week was associated with 2.4 hazard ratio for OA for men younger than 50 years.[92]

Studies examining hip OA in former athletes[93-97] noted that former champion distance runners had no more clinical or radiographic evidence of OA than did nonrunners.[89] However, another study found more radiographic changes due to degenerative hip disease in former national team long-distance runners than in bobsled competitors and control subjects.[105] In all the subjects studied, age and mileage run in 1973 were strong predictors of radiographic evidence of hip OA; for runners, running pace in 1973 was the strongest predictor of subsequent radiographic evidence of hip OA in 1988. These authors concluded that high-intensity, high-mileage running should not be dismissed as a risk factor for premature OA of the hip. Other reports found that former top-level soccer players and weightlifters, but not runners, were at risk for the development of knee OA,[79,96] but it was suggested elsewhere that former athletes seemed to be disproportionately represented in hospital admissions for OA of hip, knee, or ankle.[96] A questionnaire of former elite and track-and-field athletes noted they had increased hip OA.[95] Similarly, radiographic OA of the hip and knee was reported in women who were formerly runners and tennis players.[96] Other investigators reported no correlation between OA and running but rather with other sports, particularly soccer and tennis (where knee injuries were prevalent).[97] It was speculated that peak load per unit distance (stride and short duration of ground contact) may explain the fewer injuries and reduced prevalence of OA in running compared with certain other sports.[98]

Cross-sectional studies on the effect of weight-bearing exercise on the development of OA of the hip, knee, or ankle and foot must be interpreted with caution. The radiographic scoring methods used by each group of investigators differ, and their reliability has not been adequately tested. This information is important when the major end points in the studies are radiographic features of OA.

## PERFORMING ARTS–RELATED MUSCULOSKELETAL DISORDERS

Musculoskeletal problems are common among performing artists. Performing artists—particularly musicians and dancers—have unique medical and musculoskeletal problems that merit special consideration. Injuries that might be trivial to others may be catastrophic to such artists. These injuries are usually associated with overuse—the consequences of tissues stressed beyond anatomic or normal physical limits. Understanding the technical requirements and biomechanics required in the performance of a craft (art), as well as the lifestyle required to pursue a successful career in these fields, should help physicians appreciate causative factors that lead to these injuries.

The following principles are important in treating such patients:

- Musculoskeletal problems constitute the bulk of health issues for these persons.
- Performing artists are usually wary of consulting with physicians and skeptical of their expertise.
- An appropriate evaluation should be carried out by someone knowledgeable about the technical and biomechanical requirements of the patient's craft(s)/art(s). The evaluation should consider instrument(s), instrument usage, travel with instruments, shoes, performance surface and setting, practice and performance routines, repertoire, coaches and training/trainers, and lifestyle and psychological factors, as appropriate.
- Evaluation should include attention to joint laxity and other physical features of the artist, as well as to their relationship to performance, considering the entities encountered as listed in Table 35-7.[105-109] The evaluation should assess muscle tension and fatigue. Patients should demonstrate how they use an instrument while both the actively moving body parts and the relatively immobilized parts are examined.[105,110,111]
- Inquiry should be made about all prescription and nonprescription therapies, nutritional and exercise practices, and non-mainstream (so-called "complementary and/or alternative") treatments.
- The practitioner must have an understanding of and sympathy for the unique expectations of these performers and expertise in assessing their medical problems and developing treatment plans.
- Prevention should be emphasized—ensuring performance ability, promoting endurance and conditioning, facilitating good posture, protecting joints, maintaining proper ergonomics, and establishing appropriate exercise regimens.[110,111]
- Therapeutic interventions will usually be conservative.

### Instrumentalists

The frequency of musculoskeletal problems in musicians rivals the frequency of disability in athletes. Up to 82% of orchestral musicians have experienced medical problems (mainly musculoskeletal) related to their occupation. Up to 76% of musicians have reported a musculoskeletal issue that is grave enough to influence their ability to perform.[105,112] Woodwind players and female instrumentalists seem to be affected more often compared with other types of other instrumentalists and male artists, respectively. Muscle-tendon overuse or repetitive stress injuries, nerve entrapment problems, and focal dystonias are most common (see Table 35-7).[105,106]

The causes of, mechanisms of, and therapies for these musculoskeletal problems are unclear. Overuse, tendinitis, cumulative trauma disorder, repetitive motion disorder,

occupational cervicobrachial disorder, and regional pain syndrome have been considered critical risk factors in the development of joint laxity in musicians.[112] Joint laxity declined with age and was associated with gender, starting earlier in men but persisting in women through their mid 40s. The presence or absence of hypermobility at certain sites was associated with musicians' reports of associated symptoms. Hypermobility in musicians might produce advantages or disadvantages, depending on the site of the laxity and the instrument played.[113] Paganini, with his long fingers and reported hyperextensibility, had a wider finger reach on the violin than his contemporaries, but he may have had a predisposition to OA because of this. Of interest and seemingly unexplained was the high frequency of symptoms among women (68% to 84%); perhaps this finding is related to their higher incidence of hypermobility.[112] Stress also likely contributes to motor function problems such as occupational cramps; dealing with this issue often requires the best efforts of a team of physicians and therapists.[112-115]

## Vocal Artists

Musculoskeletal problems among singers have not been addressed extensively. The frequency of musculoskeletal problems was the same in both instrumentalists and opera singers. However, singers had more hip, knee, and foot joint complaints, perhaps reflecting the effects of prolonged standing.[114]

## Dancers

Dance has been viewed as a demanding art form. Classical ballet ranked first in activities generating physical and mental stress, followed by professional football and professional hockey. The dancer and athlete have much in common, but important differences in training and performance technique influence the nature of their injuries. Other important sociocultural differences affect their care. Professional dancers (as well as musicians and vocalists) traditionally have not been convinced that most physicians know how to effectively approach the unique issues of dance and music. Injured dancers seeking care have often been told that the treatment is to stop dancing. Others, seeking assistance with weight control, have been told to gain weight. Dancers frequently underreport their injuries and seek care from nonmedical therapists.

The incidence of reported dance-related injuries ranged from 17% to 95%.[116] The majority of injuries involved the foot, ankle, and knee. It is difficult to generalize about dance injuries because "dance" and its training, performance, and settings are so variable. Most injuries are from overuse and are rarely catastrophic, regardless of the style or setting.[112] The distribution of injuries is strongly influenced by the type and style of dance and the age and sex of the population.[113,117] A better understanding of the technical and aesthetic requirements of a dance, as well as the biomechanics involved to perform these requirements, is necessary to appreciate the type of injuries that can be sustained by dancers. For example, ballet dancers in companies whose choreography emphasizes bravura technique with big jumps and balances are more likely to experience Achilles tendinitis than are those in companies that do not have this emphasis. Men are more likely to have back injuries because of the requisite jumping and lifting, whereas women who dance *en pointe* are more prone to toe, foot, and ankle problems. Also in ballet, the most important physical feature is proper turnout of the hip, which requires maximal external rotation of the lower extremity that can result in hyperlordosis of the lumbar spine, valgus heel with forefoot pronation, and external rotation of the knee.[116,118]

Tendinitis of the flexor hallucis longus tendon, commonly known as dancer's tendinitis, may be confused with posterior tibial tendinitis because of the location of pain at the posteromedial ankle. Other dancer- and environment-related factors that increase the risk of dance-related injuries include nutritional status, improper support from footwear and floors, and their rehearsal and performance schedules.[116,118] Most dance shoes do not have a shock-absorbing sole, and some dances may be performed barefoot.[118] Traditionally constructed with paper, glue, and satin or canvas or leather, ballet pointe shoes tend to soften once broken in, thus contributing to ankle injury. Intensive rehearsals before and during the opening months of a performance season and pressures to return to work quickly after an injury must also be considered in the care of dancers.[112,118] Touring companies may encounter nonflexible surfaces, including concrete, predisposing to shin splints

and stress fractures. Stress fractures may be associated with the pressure to maintain a certain weight, resulting in amenorrhea, disordered eating, and low bone density. Physicians caring for dancers, particularly ballet dancers at any level, must be aware of the aesthetic pressures for extreme leanness and the potential health consequences. Unfortunately, the dance world is not lacking in other serious medical problems including mental illness, drug abuse, and human immunodeficiency virus infection.[112]

CHAPTER 36

# Cardiovascular Risk in Inflammatory Rheumatic Disease

Sherine E. Gabriel • Cynthia S. Crowson

**KEY POINTS**

- For nearly half a century, excess rates of cardiovascular (CV) disease have been reported among patients with inflammatory rheumatic diseases.
- CV mortality and morbidity—in particular, ischemic heart disease and heart failure—are significantly higher among persons with rheumatoid arthritis (RA) and/or systemic lupus erythematosus (SLE), and likely other autoimmune disorders as well, when compared with people in the general population of the same age who are free of these diseases.
- With the exception of smoking, the prevalence of traditional CV risk factors is not significantly elevated in persons with RA.
- Although the prevalence of some traditional CV risk factors is elevated in persons with SLE, these elevations alone are inadequate to explain the excess CV disease risk in persons with SLE.
- Some traditional risk factors, such as dyslipidemia, behave in a paradoxical manner in persons with RA and SLE, which can confuse the clinical picture, particularly for risk assessment.
- The systemic inflammation and immune dysfunction that characterize rheumatic diseases appear to be a major driver of CV disease risk in these patients.
- The relationship between rheumatic drugs and CV disease risk is difficult to disentangle because of confounding by indication/contraindication.

For nearly half a century, excess rates of cardiovascular (CV) disease (CVD) have been reported among people with inflammatory rheumatic diseases.[1-3] More recently, the discovery of the inflammatory and immune mechanisms underlying atherosclerosis has spurred renewed interest in the association between CVD risk and the rheumatic diseases. In this chapter we review biologic mechanisms underlying CV comorbidity in the rheumatic diseases and discuss the risks of these diseases, especially in rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). We also discuss the contribution of traditional and nontraditional CV risk factors to the observed excess CVD risk.

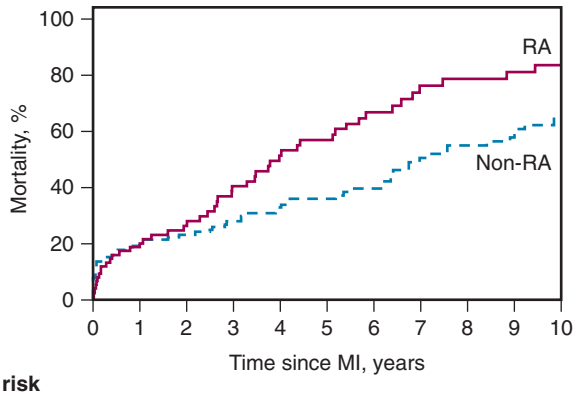
## BIOLOGIC MECHANISMS: RELATIONSHIP BETWEEN INFLAMMATION AND CARDIOVASCULAR DISEASE

The role of inflammation in the development of heart disease has only been recognized relatively recently. Rheumatic disease can be viewed as a "natural experiment" in the interplay between chronic inflammation and CVD, which could elucidate the fundamental mechanisms by which inflammation accelerates the development of atherosclerosis and heart disease. RA, SLE, Sjögren's syndrome, systemic scleroderma, inflammatory myositis, and psoriatic arthritis are characterized by chronic inflammation in various body systems, most often the joints, skin, eyes, lungs, and kidneys, but also in the heart and vascular system. RA is the most common and best studied of the autoimmune rheumatic diseases. The immune underpinnings of CVD and of RA share many similarities. Circulating acute-phase reactants, such as C-reactive protein (CRP), are elevated in persons with RA and are risk markers for heart disease in the general population. Emerging evidence suggests that T lymphocytes play a crucial pathogenic role in both RA and CVD.[4,5] The major risk gene for RA, *HLA-DRB1*, predisposes to disease by promoting the selection and survival of autoreactive $CD4^+$ T cells. HLA-DRB1 alleles are also associated with increased risk of myocardial infarction (MI) and various forms of non–RA-associated heart disease. T cells isolated from the joints of patients with RA have enhanced production of IFN-γ and interleukin (IL)-17, which presumably mediate chronic inflammation.[6,7] The proven efficacy of antagonizing T cell co-stimulation is perhaps the most compelling evidence that T cells are pathogenic in RA.[8] Similarly, percutaneous stents that elute T cell inhibiting drugs (e.g., sirolimus) prevent in-stent restenosis and repeat revascularization in people with coronary artery disease (CAD).[9]

In people with either RA or CVD, $CD4^+$ T cells characteristically lose expression of the co-stimulatory molecule, CD28, which ordinarily provides the "second signal" required for T cell activation. So-called "$CD28^{null}$" T cells are believed to have undergone reprogramming, leading to premature senescence.[10,11] Expansion of these senescent T cells among persons with RA is associated with extraarticular inflammatory manifestations, including vasculitis and lung disease, as well as CAD.[10,11] In the setting of heart disease, $CD28^{null}$ T cells are identified in atherosclerotic plaque, where they are believed to contribute to the inflammatory process by producing cytokines and by killing vascular smooth muscle cells.[12] Interestingly, *HLA-DRB1*, the aforementioned RA-risk gene, also predisposes to expansion of $CD28^{null}$ T cells in RA and in CAD.[13]

Premature senescence of T cells in RA appears to be caused by fundamental defects in the hematopoietic system.

$CD34^+$ hematopoietic progenitor cells have accelerated telomere erosion, a sign of senescence.[14] Naïve T cells in persons with RA also are prematurely aged, with increased fragility and damage of their DNA because of insufficient activity of basic DNA repair enzymes.[15] Similarly, telomere shortening in hematopoietic progenitor cells correlates with myocardial dysfunction in persons with CAD.[16] The onset of both RA and CVD coincides with the loss of thymic emigration of naïve T cells in the fifth decade, suggesting that T cell senescence may underlie the pathogenesis of both of these age-associated conditions. In the foreseeable future, rejuvenation of senescent T cells with use of new drugs that restore genomic repair and integrity has the potential to be an effective strategy for the prevention and treatment of CVD.[17]

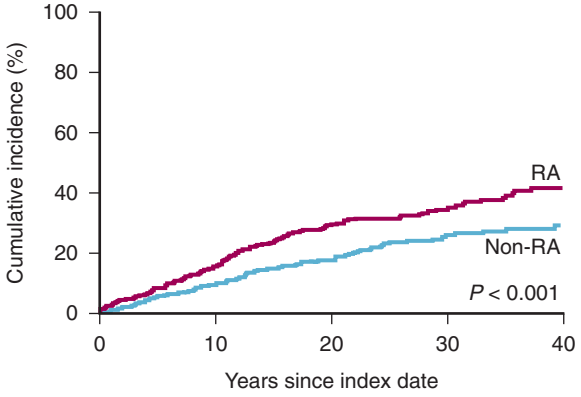


## CARDIOVASCULAR MORBIDITY IN RHEUMATOID ARTHRITIS AND SYSTEMIC LUPUS ERYTHEMATOSUS

### Rheumatoid Arthritis

#### Ischemic Heart Disease in Rheumatoid Arthritis

Patients with RA are at increased risk of ischemic heart disease (IHD).[3,18-20] Data from the Rochester Epidemiology Project has shown that, in the 2-year period immediately preceding the fulfillment of the American College of Rheumatology (ACR) 1987 criteria, persons with RA were more likely to experience hospitalization for MI (odds ratio [OR], 3.17; 95% confidence interval [CI], 1.16 to 8.68) and unrecognized ("silent") MI (OR, 5.86; 95% CI, 1.29 to 26.64) than age- and sex-matched control subjects. The increased risk of unrecognized MI persisted after the diagnosis of RA (hazard ratio [HR], 2.13; 95% CI, 1.13 to 4.03). Holmqvist et al.[21] failed to demonstrate a statistically significant elevated increase in MI, angina, or heart failure (HF) prior to the onset of symptoms in two large Swedish cohorts, although trends toward such elevation were reported. As in studies of mortality, these results suggest that accelerated atherosclerosis begins at the onset of RA symptoms, or even earlier, and not at the time of diagnosis or later in the disease course.



Patterns of clinical care and outcome after MI may vary in persons with RA when compared with the general population. Some evidence suggests that, although patients with RA receive MI care that is similar to that received by patients without RA, they experience higher rates of HF and death after sustaining an MI (Figure 36-1).[20,22,23] However, other investigators have reported that patients with RA who experience acute MI receive acute reperfusion and secondary prevention medications (including β-blockers and lipid-lowering agents) less frequently than do control subjects.[24] Another group recently reported that among patients with MI, those with RA were more likely to undergo thrombolysis and percutaneous coronary intervention (PCI) but were less likely to receive medical therapy and/or coronary artery bypass grafting.[25] That study also suggested that patients with RA may have an in-hospital survival advantage, particularly those undergoing medical therapy and PCI, although potential confounding could not be ruled out.

#### Heart Failure in Rheumatoid Arthritis

Persons with RA are at increased risk of developing HF compared with the general population.[26,27] In the Rochester RA cohort, the cumulative incidence of HF (defined according to the Framingham criteria) at 30-year follow-up was 34%, compared with 25% in the non-RA cohort (Figure 36-2).[27] Even after adjustment for demographics, CV risk factors, and IHD, patients with RA had almost twice the risk of developing HF as subjects without RA (HR, 1.87; 95% CI, 1.47 to 2.39). This increased risk of HF appeared to be predominantly in the subgroup of patients with rheumatoid factor (RF) who were $RF^+$; the HR in $RF^+$ patients was 2.59 with a 95% CI of 1.95 to 3.43, whereas the HR in $RF^-$ patients was 1.28 with a 95% CI of 0.93 to 1.78.

The clinical presentation of HF in patients with RA differs from that of HF in patients without RA.[28] Patients with RA who have HF are less likely to be obese or hypertensive or have clinical IHD. Moreover, patients with RA who have HF are less likely to have typical signs and symptoms. Importantly, the proportion of patients with HF who have preserved ejection fraction (>50%) is significantly higher among patients who have RA compared with patients who do not have RA (Figure 36-3).[28]

It has also been shown that patients with RA who have HF tend to undergo less aggressive investigation and be managed less aggressively than patients without RA.[28] Finally, patients with RA who have HF also appeared to have poorer outcomes (Figure 36-4), experiencing approximately twice the risk for death in the period immediately after HF identification compared with patients who do not have RA.[29]

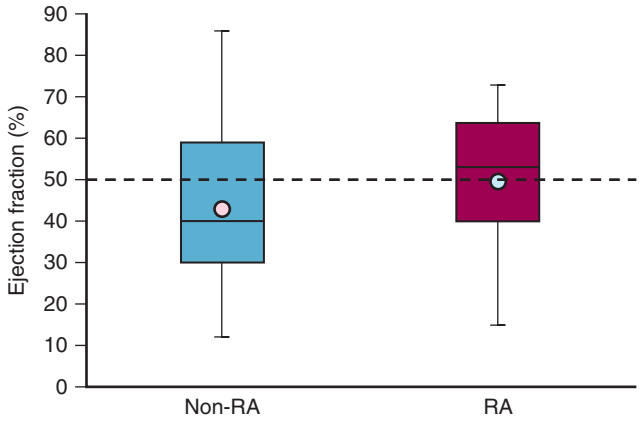

**Figure 36-3** Distribution of ejection fraction (EF) between patients with and without rheumatoid arthritis (RA) at the onset of heart failure. Data are presented as box plots, with the *boxes* representing the 25th to 75th percentiles, the *vertical lines* representing the 10th and 90th percentiles, the *circles* representing the means, the *lines within the boxes* representing the medians, and the *broken line* representing the 50% EF reference. *(From Davis JM, Roger VL, Crowson CS, et al: The presentation and outcome of heart failure in patients with rheumatoid arthritis differs from that in general population.* Am Coll Rheumatol *58:2603–2611, 2008. ## Systemic Lupus Erythematosus

### Ischemic Heart Disease in Systemic Lupus Erythematosus

Accelerated atherosclerosis is an established complication of SLE.[30-35] The prevalence of atherosclerotic vascular events varies from 1.8% early in the course of the disease to more than 27% later in the course of SLE.[34] The majority of studies reported increased risk of MI ranging from twofold to greater than 10-fold in various SLE patient groups compared with the general population.[33,34,36] This increased relative risk (RR) of MI is particularly apparent in younger patients with SLE. The most striking example comes from the University of Pittsburgh lupus cohort, in which women with SLE aged 35 to 44 years were more than 50 times as likely to have an MI compared with women without SLE in the Framingham Offspring study (RR, 52.43; 95% CI, 21.6 to 98.5).[34] Furthermore, the majority (67%) of women with SLE were younger than 55 years at the time of their first cardiac event. In addition, a more than twofold increased risk of hospitalizations for MI has been reported in young women with SLE between the ages of 18 and 44 years compared with persons without SLE (OR, 2.27; 95% CI, 1.08 to 3.46).[37,38] As in RA, it appears that the increased risk of CVD among persons with SLE may begin before the diagnosis of SLE (OR, 3.7; 95% CI, 1.8 to 7.9), as recently reported in a population-based study of 70 patients who had SLE compared with 2565 patients who did not have SLE.[39] The risk of CVD and mortality was also shown to be increased 10-fold among women with SLE who had successful deliveries, despite the rarity of CVD among women of reproductive age.[40]

In a recent study of patients undergoing coronary revascularization procedures, no significant differences were found in the mean percentage of coronary stenosis and total occlusion in subjects with and without SLE.[41] Except for the increased likelihood of lesions confined to the left anterior descending artery in subjects with SLE versus subjects without SLE (42% vs. 19%; $P = 0.003$), the pattern of coronary involvement, including artery dominance and prevalence of multivessel disease, appeared similar in subjects with SLE versus subjects without SLE. However, the study reported significantly worse CV outcomes at 1 year after PCI in subjects with SLE versus subjects without SLE, including higher risk of MI (16% vs. 5%; $P = 0.01$) and repeat PCI (31% vs. 12%; $P = 0.009$) in persons with SLE, even after adjustment for important covariates.[37,41] Given the increased vulnerability of atherosclerotic plaque in persons with SLE, which is associated with the risk of occlusive events irrespective of the size of the plaque, these findings suggest an increased risk of unfavorable CV events in persons who had SLE compared with persons who did not have SLE with a seemingly similar pattern of coronary involvement.[42]

A large population-based study from 1996 to 2000 of patients hospitalized in California with acute MI showed that in-hospital mortality and length of stay were essentially

similar in patients who had SLE compared with patients who did not have SLE, adjusting for age, race, ethnicity, type of medical insurance, and Charlson Index. In contrast, data from the 1993-2002 U.S. Nationwide Inpatient Sample showed significantly increased rates of in-hospital mortality (RR, 1.46; 95% CI, 1.31 to 1.61) and prolonged hospitalization (RR, 1.68; 95% CI, 1.43 to 2.04) for acute MI in persons who had SLE compared with control subjects, adjusting for age, sex, race/ethnicity, income, and HF.[37] Some differences in methodology (i.e., a smaller sample size and older age of patients with SLE and control subjects in the earlier study and a shorter observation period in the later study) may at least in part explain these contrasting results. Considering the presence of myocardial involvement, chronic systemic inflammation, vasculitis, and hyperviscosity syndrome in SLE, worse outcomes after acute coronary events and associated interventions can reasonably be expected.[43] However, further study is required.

### Heart Failure in Systemic Lupus Erythematosus

The risk of HF and related hospitalization in persons with SLE appears to be substantially increased.[37,38] In particular, young women with SLE between the ages of 18 and 44 years have more than a 2.5-fold increased risk of hospitalization for HF compared with persons who do not have SLE, even after adjustment for age, race, insurance status, hospital characteristics, and the presence of hypertension, diabetes mellitus, and chronic renal failure.[44] The nature of HF in SLE is likely multifactorial and only partly attributable to atherosclerosis.[45,46] The presentation of HF in persons with SLE may vary from severe overt HF to insidious myocardial involvement.[45-49] Finally, mortality in patients with SLE who have HF is significantly higher than in patients without HF (18% vs. 6%, $P < 0.001$) and approximates 3.5-fold compared with patients who have HF in the general population.[37,45]

## CARDIOVASCULAR MORTALITY IN RHEUMATOID ARTHRITIS AND SYSTEMIC LUPUS ERYTHEMATOSUS

### Rheumatoid Arthritis

It is well known that the mortality of patients with established RA is higher than that of the general population. A meta-analysis of 24 mortality studies in persons with RA that were published between 1970 and 2005 reported a weighted combined all-cause standardized mortality ratio (met-SMR) of 1.50 (95% CI, 1.39 to 1.61), with similar increases for IHD (met-SMR, 1.59; 95% CI, 1.46 to 1.73) and stroke (met-SMR, 1.52; 95% CI, 1.40 to 1.67) and for men (met-SMR, 1.45) and women (met-SMR, 1.58).[50-52] Approximately 50% of all deaths in subjects with RA are attributable to CV causes, including IHD and stroke,[53] and CVD appears to occur earlier in persons with RA. The latter observation is consistent with the recent hypothesis of accelerated aging in persons with RA.[54] Moreover, persons with RA frequently experience "silent" IHD and/or silent MI—that is, showing no symptoms at all before a sudden cardiac death. Sudden cardiac deaths are almost twice as common in patients with RA as in the general population (HR, 1.99; 95% CI, 1.06 to 3.55).[18]

The excess CVD mortality related to RA may be confined to, or at least be substantially higher, in subjects who are $RF^+$.[55-57] The link may be even stronger with anti-citrullinated protein antibody (ACPA) positivity.[58] As might be expected, the RR of CVD mortality is highest in younger age groups (persons younger than 55 years) and in women, whereas the attributable risk is highest in the oldest age groups and in men.[19,56,59]

Controversy persists regarding how soon after symptom onset the excess CVD mortality risk becomes apparent and/or whether there is a secular trend toward improving CVD mortality in persons with RA (as is seen in the general population). This controversy may in part be explained by differences in the period of follow-up—that is, follow-up starting from the time of symptom onset, from a physician's diagnosis of RA, or from the date of fulfillment of ACR criteria or other diagnostic criteria. The latter may not occur until some years after the first symptoms appear. In the Norfolk Arthritis Register (NOAR), the excess CVD mortality is detectable beginning around 7 years after symptom onset.[55] In a Dutch inception cohort of 1049 patients with RA recruited between 1985 and 2007, excess mortality became apparent at around 10 years from diagnosis (with all subjects having <1 year symptom duration).[60] Emerging evidence indicates that mortality may be improving among persons with RA, but CV mortality has also improved in the general population, and thus the relative increase in CV mortality has not changed over time. [61] A meta-analysis that included 17 studies (91,916 patients) also showed no trend toward improving CVD mortality with time.[62]

### Systemic Lupus Erythematosus

As first described by Urowitz et al.[2] in 1976, mortality in SLE appears to follow a bimodal pattern, with an early peak in mortality (within 1 year of diagnosis) and a later peak occurring more than 5 years after diagnosis. Reported survival in the first 5 years of SLE has improved considerably from about 50% in the 1950s to greater than 90% in the 1990s.[63] However, there is some question about whether this improvement may be due, at least in part, to earlier diagnosis and improved ascertainment of mild cases. In the Toronto lupus cohort of 1241 patients recruited between 1970 and 2005, the SMR improved from 13.84 (95% CI, 9.78 to 19.76) during 1970-1978 for those who entered the cohort in that decade to 3.81 (95% CI, 1.98 to 7.32) during 1997-2005 in persons who entered the cohort in that period.[64] The SMR during 1997-2005 was very similar for patients regardless of their disease duration, ranging from 3.23 for those who had entered the cohort in 1970-1978 to 3.93 for those who had entered the cohort in 1988-1996. Similarly, evidence from Olmsted County showed an SMR of 2.70 with significant improvement in survival in recent decades.[65] In a study of 434 female patients with SLE from Seoul, Korea, who were followed up from 1992 to 2002, the SMR was 3.02 (95% CI, 1.45 to 5.55).[66] A recent population-based cohort study of 70 patients with incident SLE in 1991-2008 reported nearly twofold increased mortality and increased CVD rates. In addition, increased mortality and

CVD event rates were found perioperatively in women with SLE who were undergoing surgical procedures, even for low-risk procedures (OR, 1.54; 95% CI, 1.00 to 2.37).[67]

## RISK FACTORS FOR CARDIOVASCULAR DISEASE

Evidence for the pivotal role of inflammation in driving increased CVD risk in persons with RA is compelling. Yet, despite improved control of inflammation, CVD risk among people with RA remains elevated. Moreover, the identification of clinically valuable biomarkers of CVD risk in persons with RA remains elusive.[68] In the next sections we highlight recent evidence and discussions regarding the relative contribution of traditional and nontraditional risk factors (e.g., markers of inflammation and RA features) toward the excess CVD risk in persons with RA and suggest directions for future research.[69]

### Traditional Cardiovascular Risk Factors in Rheumatoid Arthritis: Occurrence and Impact

The role of traditional risk factors in the development of CVD in persons with RA is an area of active research. One possible explanation for the increase in CVD seen in persons with RA could be that the traditional CVD risk factors are more common in persons with RA or that they are as common but more deleterious. Alternatively, the excess CVD risk may be explained by the adverse impact of the inflammatory and immune changes of RA on the vessel wall. It is most likely, however, that traditional risk factors and inflammation are intimately interconnected and perhaps act synergistically (Figure 36-5).[70] Indeed, one study showed that progression of a new CV event in subjects with early RA may be predicted by traditional CV risk factors but precipitated by high disease activity.[71]

#### Smoking in Persons with Rheumatoid Arthritis

Smoking is a known risk factor for the development of RA, in particular $RF^+$ and $ACPA^+$ RA.[72] Thus, as expected, there is a higher prevalence of current and ex-smokers among subjects with RA than among the general population. In a meta-analysis of four case-control studies of traditional CVD risk factors in RA including 1415 patients with RA, the prevalence of smoking was found to be significantly higher than in control subjects (OR, 1.56; 95% CI, 1.35 to 1.80).[73] Smokers with RA also appear to have higher RF titers and a worse prognosis in terms of disability, radiographic damage, and treatment response.[74] A known interaction exists between smoking, HLA-DR1 shared epitope (SE) alleles, and the production of ACPA[75] and between smoking, ACPA, and the SE in premature CVD mortality in RA.[76]

#### Hypertension in Rheumatoid Arthritis

Hypertension is common in persons with RA, but it remains unclear whether it is more common than in the general population. Whereas some studies have found hypertension to be an important risk factor for CVD in persons with RA,[77] a recent meta-analysis of seven case-control studies (1053 patients with RA) found the prevalence of hypertension to be the same in persons with RA as in control subjects (OR, 1.09; 95% CI, 0.91 to 1.31).[73] However, some evidence exists for underdiagnosis and undertreatment of

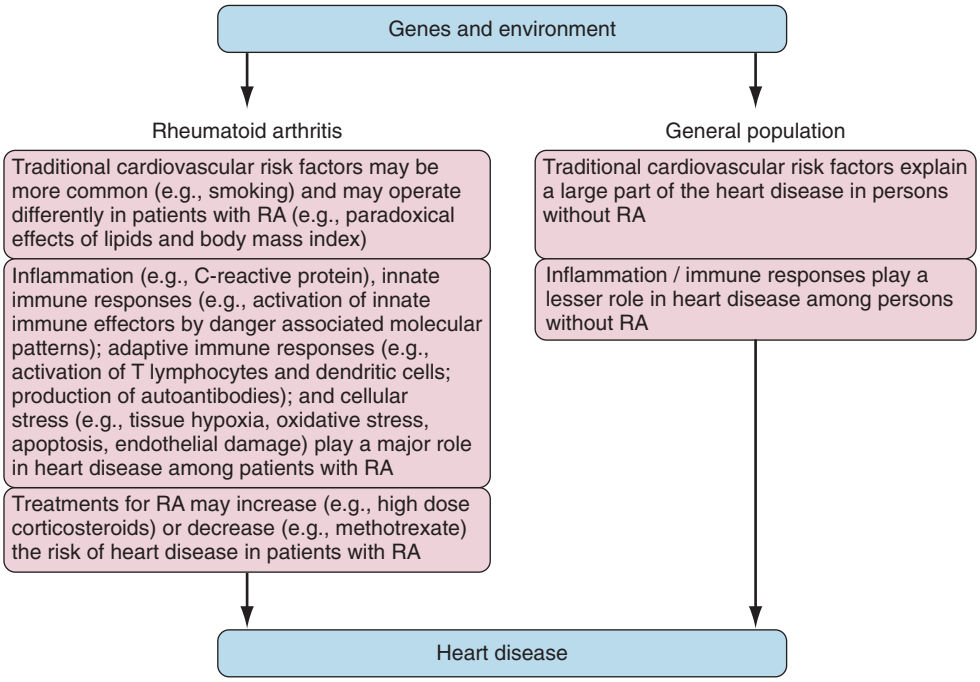

**Figure 36-5** Why do patients with rheumatoid arthritis (RA) develop heart disease? Determinants of heart disease in patients with RA differ from the general population. *(From Crowson CS, Liao KP, Davis JM, et al: Rheumatoid arthritis and cardiovascular disease.* Am Heart J *166:622–628, 2013. Permission to reprint from Elsevier.)*

hypertension in persons with RA.[78] Multiple other factors may influence blood pressure control in persons with RA, including physical inactivity, obesity, specific genetic polymorphisms, and some anti-rheumatic medications, including nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, leflunomide, and cyclosporine.

### Dyslipidemia in People with Rheumatoid Arthritis

Although findings have been somewhat inconsistent, hyperlipidemia appears to have a paradoxical effect on CVD risk in persons with RA, whereby decreased lipid levels are associated with increased CVD risk (Figure 36-6).[79,80] Serum levels of total cholesterol and low-density lipoprotein (LDL) cholesterol decline precipitously during the 3- to 5-year period prior to RA incidence,[81] and lower total and LDL cholesterol levels have been shown to be associated with higher CVD risk.[80] Suppression of total and LDL cholesterol levels during acute or chronic high-grade inflammation is well described, as is a proportionately greater suppression of high-density lipoprotein (HDL) cholesterol, resulting in a disadvantageous atherogenic index (total: HDL cholesterol ratio).[82] This phenomenon may explain why hyperlipidemia (high total or LDL cholesterol) appears to be less common in persons who have RA compared with subjects who do not have RA.[79,83,84] Indeed, even among patients who sustained a previous MI, those with RA had significantly lower levels of total and LDL cholesterol than did those without RA.[85] Dyslipidemia (i.e., alterations of individual lipid components and their ratios as defined by specific criteria) may affect up to half of all patients with RA.[86] A recent meta-analysis showed that RA is associated with an abnormal lipid pattern, principally low levels of HDL cholesterol.[87] In vitro, animal model, and in vivo human studies clearly demonstrate that the interplay between inflammation and lipid components is far more complex than simple alterations of their serum levels (Figure 36-7). [88]

Inflammation-induced alterations of the structure and function of lipid molecules require further study, specifically in persons with RA and in the context of disease control through nonbiologic and biologic disease-modifying anti-rheumatic drugs (DMARDs).[89] Several studies suggest anti-rheumatic therapy effects on lipid levels, including glucocorticoids, hydroxychloroquine, gold, and cyclosporine, as well as the biologics anti–tumor necrosis factor (TNF), rituximab, and tocilizumab.[90] However, these studies are of short duration, and more research is needed. Multiple other factors are involved in lipid regulation and function,

including physical activity, adiposity, diet, alcohol intake, and smoking. However, their effects have not been assessed in sufficient detail in persons with RA. Similarly, the importance of genetic regulation of lipid metabolism, particularly in the context of gene-environment interactions, has not been addressed in the RA population. This factor may be particularly important because lipid alterations appear to predate the diagnosis of RA.[91] Although the relationships between lipids and CVD in RA are complex, the value of primary lipid screening in persons with RA is undisputed. Unfortunately, evidence suggests an unacceptable low rate of primary lipid screening and of statin use in persons with RA.[86,92,93]

### Diabetes Mellitus and Metabolic Syndrome in Rheumatoid Arthritis

A recent meta-analysis of seven case-control studies (1230 patients with RA) reported that the prevalence of diabetes mellitus was increased in comparison with control subjects (OR, 1.74; 95% CI, 1.22 to 2.50).[73] Likewise, patients with RA were significantly more likely to have metabolic syndrome than were subjects who did not have RA.[94,95] Abdominal obesity, anti-hypertensive medication, disease activity, and use of corticosteroids all affect glucose metabolism in RA.[96] On the other hand, use of hydroxychloroquine has been shown to reduce the risk of developing diabetes mellitus in persons with RA by approximately 77%.[97]

### Body Composition/Obesity in Rheumatoid Arthritis

Escalante and colleagues[98] reported a "paradoxical effect of BMI on survival in persons with RA," demonstrating that as body mass index (BMI) declined, so did survival probability among study subjects with RA. Among persons without RA, low BMI is not associated with increased risk of CV death. However, among patients with RA, low BMI, which may indicate uncontrolled active systemic inflammation, is associated with a threefold increased risk of CV death[99] even after adjustment for cardiac history, smoking, diabetes mellitus, hypertension, and malignancy.

Obesity is associated with the development of RA.[100,101] Obesity is also associated with an increased frequency of traditional CV risk factors in patients with RA.[102] In particular, abdominal fat is associated with insulin resistance and inflammatory load in patients with RA, and new evidence indicates that in such patients, abdominal fat is distributed differently between the visceral and subcutaneous compartments, with visceral fat more strongly associated with cardiometabolic risk.[103,104] Adipose tissue is metabolically active and, through a network of adipocytokines, regulates not only energy intake and expenditure but also inflammation. Interventions to reverse rheumatoid cachexia, control obesity, and regulate insulin resistance, including comprehensive physical exercise programs, in persons with RA have been inadequately studied.

## Nontraditional Cardiovascular Risk Factors in Rheumatoid Arthritis: Occurrence and Impact

Rheological characteristics such as whole blood viscosity, plasma viscosity, erythrocyte deformability, aggregation, and erythrocyte nitric oxide (NO) production have been increasingly linked to CVD risk in the general population.[105-107] A recent study showed that whole blood viscosity and erythrocyte NO production are independently associated with subclinical atherosclerosis in women with RA who did not have previous CV events.[108] The study also documented disturbed and unfavorable hemorheological features in association with disease activity and with traditional CV risk factors. Thus abnormal rheological characteristics of blood might represent important, nontraditional risk factors pointing to a different mechanism that may contribute to atherogenesis in inflammatory rheumatic diseases. Likewise, cytokines such as IL-17, IL-6, and TNF,[109,110] as well as wider cytokine/chemokine profiles, may play a role.[111]

### The Impact of Rheumatoid Arthritis Disease Activity and Severity on Cardiovascular Co-Morbidity

A number of studies have linked risk of CV comorbidity with markers of RA disease activity such as baseline CRP and erythrocyte sedimentation rate (ESR).[18,112] In a study of 231 male veterans with RA, a baseline disease activity score (DAS28) greater than or equal to 5.1 predicted CV events (HR, 1.3; 95% CI, 1.1 to 1.6).[113] Markers of disease severity such as RF, ACPA, physical disability, destructive changes on joint radiographs, rheumatoid nodules, vasculitis, rheumatoid lung disease, and corticosteroid use are statistically significantly associated with increased risk of CV events and/or death even after adjustment for traditional CV risk factors.[58,114-118] Analyses of ESR levels in 172 persons with RA who had HF demonstrated that the proportion with significantly elevated ESR (≥40 mm/h) was highest during the 6-month period prior to HF diagnosis compared with any other time over the entire follow-up period (Figure 36-8).[114] RF and ANA have also been shown to be risk factors for MI, HF, and/or vascular disease, even in subjects without RA, suggesting that immune dysregulation may

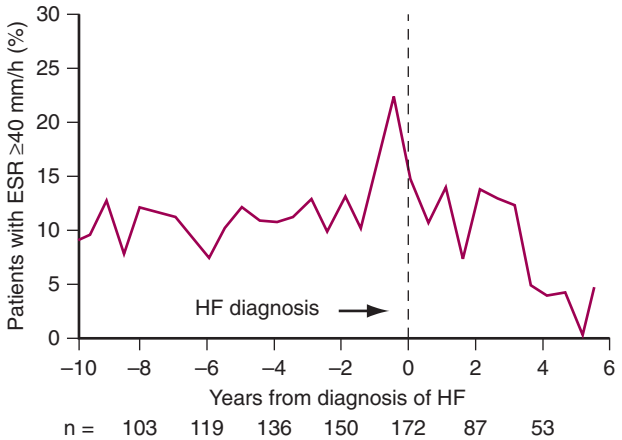

**Figure 36-8** Proportion of patients with rheumatoid arthritis with erythrocyte sedimentation rate (ESR) greater than 40 mm/h during the 6-month intervals before and after the heart failure (HF) incidence date (among 172 patients with rheumatoid arthritis who experienced heart failure). n, the number of patients under observation within the interval. *(Maradit-Kremers H, Nicola PJ, Crowson CS, et al: Raised erthrocyte sedimentation rate signals heart failure in patients with rheumatoid arthritis.* Ann Rheumatic Dis *66:76–80, 2007. Permission to reprint from BMJ Publishing Group LTD.)*

promote CVD risk not only in persons with rheumatic disease but also in the general population.[115]

### Medications as Cardiovascular Risk Factors

Medications used for the treatment of rheumatic diseases may also affect CVD risk. Because of the common use of NSAIDs and concerns surrounding CVD risk with their use, this subject has been extensively studied. Although some evidence indicates that NSAID use[119] is not associated with increased CVD risk in persons with RA, a recent network meta-analysis of 31 trials in 116,429 patients concluded that there is little evidence to suggest that any of the investigated drugs (i.e., naproxen, ibuprofen, diclofenac, celecoxib, etoricoxib, rofecoxib, or lumiracoxib) are safe.[120] In contrast, use of DMARDs (methotrexate in particular) and/or biologic agents has been suggested to decrease CVD risk[121-125] and, perhaps, to improve endothelial function (Figure 36-9).[70,126] This outcome is believed to be due to the effective long-term control of systemic inflammation. Although these findings are intriguing, they cannot be considered definitive evidence that these agents reduce CVD risk because of confounding by indication and/or contraindication. Statins have established effectiveness in the primary prevention of CV events in the general population and at-risk subpopulations (e.g., patients with diabetes mellitus). These agents have both lipid modifying and anti-inflammatory effects. However, their role in RA has only more recently been explored.[86,127]

## Traditional and Nontraditional Cardiovascular Risk Factors in Systemic Lupus Erythematosus

It is well known that traditional risk factors confer important CVD risk in the general population. Patients with SLE have an increased prevalence of several of these risk factors, including sedentary lifestyle, elevated very low density lipoprotein cholesterol and triglycerides, smoking, premature menopause, chronic renal impairment, hypertension, hyper-homocystinemia, metabolic syndrome, and insulin resistance.[128-133] Nonetheless, traditional CV risk factors cannot alone explain the observed excess risk of premature and accelerated CVD in patients with SLE. Recent research clearly demonstrates that nontraditional risk factors are major contributors to this excess risk. The most reproducible nontraditional CVD risk factors in patients with SLE include disease activity, disease duration, and corticosteroid use. The genetics of CVD in patients with SLE have not been clearly elucidated; however, early findings point to predictor single nucleotide polymorphisms, which also confer risk of thrombosis in the general population.[134] Several biomarkers have been associated with CVD risk in SLE, including autoantibodies such as anti-phospholipid antibody (aPL) antibodies, autoantibodies directed against apolipoprotein A, HDL and heat shock protein,[135-138] as well as pro-inflammatory HDL and high-sensitivity CRP. IFNs have received particular attention as mediators of disease pathogenesis and even as treatment targets in SLE. It is now increasingly recognized that by promoting endothelial injury and failed repair during SLE disease flares, IFNs may also have a profound impact on CVD risk.[139,140] As is the case in RA, SLE therapeutics likely have mixed effects on CVD risk. Although it is well known that duration of corticosteroid use is an independent predictor of CVD in patients with SLE, it is also clear that aggressive immunosuppressive and anti-inflammatory therapy correlates with reduced CVD burden.[35] Among all SLE therapeutics, the strongest evidence for a vasculo-protective effect exists with antimalarial agents.[141] These agents have been shown to be associated with reduced vascular stiffness, decreased carotid plaque, and lower cholesterol levels in addition to a protective effect on thrombovascular events.[142,143] Although some evidence suggests that mycophenolate mofetil may also protect against CVD in patients with SLE, these findings are less consistent than those reported with antimalarial drugs.[144] Despite this large and growing body of evidence regarding risk factors for CVD in patients with SLE, no randomized controlled trials (RCTs) have been performed to test preventive CVD strategies in this patient population. Thus management of risk factors must be individualized for each patient who has SLE, with prompt treatment of modifiable traditional risk factors (including use of statins, where indicated), careful monitoring of SLE therapeutics, and aggressive treatment of the underlying disease process.

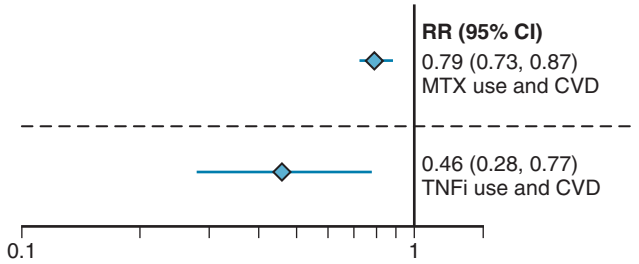

**Figure 36-9** Estimated relative risks (RRs) from meta-analyses on observational data for cardiovascular disease (CVD) risk in patients with rheumatoid arthritis associated with methotrexate (MTX) use and CVD risk associated with TNF inhibitor (TNFi) use. # CARDIOVASCULAR MORTALITY, MORBIDITY, AND RISK FACTORS IN OTHER RHEUMATIC DISEASES

## Ankylosing Spondylitis

Ankylosing spondylitis (AS) represents the prototype of the spondyloarthropathies and is characterized by axial disease, enthesitis, and oligoarthritis. Although the risk of CVD in persons with AS has not been as well defined as in persons with RA, awareness of the risk of CVD in this population has been heightened.[145-148] As authors of a recent retrospective cohort study using population-based administrative data from 8616 subjects with AS reported, the sex standardized prevalence ratio for IHD was 1.37 (95% CI, 1.31 to 1.44), and for HF it was 1.34 (95% CI, 1.26 to 1.42).[146]

## Psoriasis and Psoriatic Arthritis

Both psoriasis and psoriatic arthritis have been shown to be associated with an increased risk of CVD relative to the

general population. The prevalence of traditional CV risk factors has been demonstrated to be higher among patients with psoriasis, but even after adjusting for these variables, the risk of IHD remains high (OR, 1.78; 95% CI, 1.51 to 2.11), with recent studies suggesting that psoriasis may be an independent risk factor for MI.[149-151] Persons with psoriatic arthritis are more likely to have evidence of pre-clinical atherosclerosis and are at increased risk of CVD relative to the general population.[148,152-154] Among 648 patients with psoriatic arthritis enrolled in the University of Toronto database, the risk of MI (standardized prevalence ratio 2.57; 95% CI, 1.73 to 3.80) and angina (standardized prevalence ratio 1.97; 95% CI, 1.24 to 3.12) was significantly higher than that of the general population, with increased risk seen in patients with more severe psoriasis.[155]

### Giant Cell Arteritis and Polymyalgia Rheumatica

Whether the risk of CVD is increased among patients with giant cell arteritis is less clear. Authors of two population-based studies reported two- to threefold increased risk, and authors of another study reported no increased risk.[156-158] The risk of CVD among patients with polymyalgia rheumatica has not been well studied. Authors of a few studies have reported increased risks for CVD in patients with polymyalgia rheumatica that are similar to the risk levels reported in other inflammatory diseases.[159,160] However, a recent systematic review found heterogeneity between studies that precluded a formal meta-analysis, suggesting that more research is needed to definitively determine whether the risk of CVD is increased among patients with polymyalgia rheumatica.[161]

### Dermatomyositis and Polymyositis

Because large epidemiologic studies of CVD risk in patients with myositis are lacking, the frequency of CVD in patients with myositis is not clear, but cardiac involvement is well recognized as a clinically important manifestation of myositis.[162] A recent report utilizing the Nationwide Inpatient Sample found that one-fifth of dermatomyositis hospitalizations in the United States were associated with an atherosclerotic CV diagnosis or procedure and that patients with dermatomyositis and CVD have twice the risk of in-hospital death compared with control subjects and patients who have dermatomyositis without CVD.[163] In a Canadian study, high rates of CVD were found among patients with dermatomyositis and polymyositis (13 per 1000 person-years for MI); these rates were higher compared with data from the general population of Canada.[164] Of note, use of DMARDs was associated with a reduced risk of arterial events (adjusted RR, 0.5; 95% CI, 0.2 to 1.0), which suggests that controlling systemic inflammation could reduce the risk of CVD.[165]

### Osteoarthritis

Although osteoarthritis is the most common rheumatic disease, very little is known about the link between osteoarthritis and CVD. Osteoarthritis may be associated with an increased risk of CVD because of its associated synovial inflammation and muscle weakness or because it leads to less physical activity and to NSAID use, which are all associated with increased risk of CVD.[166] Rahman et al.[166] found that osteoarthritis increased the risk of IHD (RR, 1.30; 95% CI, 1.19 to 1.42) and HF (RR, 1.15; 95% CI, 1.04 to 1.28). Hawker et al.[167] found that patients with more severe osteoarthritis were at higher risk for CV events than those with milder diseases.

### Pediatric-Onset Rheumatological Diseases

CVD has been difficult to study in patients with pediatric-onset rheumatologic disease, such as juvenile idiopathic arthritis, pediatric-onset SLE, and juvenile dermatomyositis, because CV events are rare at young ages.[168] Surrogate measures of CVD, such as flow-mediated dilatation, carotid intima media thickness, and pulse wave velocity have recently been used to explore CVD in children with pediatric-onset rheumatologic diseases. Studies of these measures of subclinical CVD and of lipids have shown increased levels among children with juvenile idiopathic arthritis, pediatric-onset SLE, and juvenile dermatomyositis.[169-173] It is likely that these patients will experience significant CVD morbidity and mortality in adulthood. More studies are needed to better define the increased risk of CVD among patients with pediatric-onset rheumatologic diseases and to design and test preventive strategies to circumvent this eventuality and improve the long-term outcomes of these patients.

Although data on the increased risk of CVD among patients with less widely studied inflammatory rheumatic diseases is still emerging, CVD has been recognized as an important contribution to increased mortality and morbidity in this patient population and represents an area of ongoing research.[174]

## CARDIOVASCULAR RISK ASSESSMENT

As previously noted, both traditional and nontraditional risk factors affect the development of CVD in persons with RA and SLE. Traditional CV risk factors alone cannot account for the increased risk of CVD in these patients.[33,175] This information, together with the findings that traditional CV risk factors behave differently in patients with RA and SLE compared with the general population, suggests that risk scores based on traditional CV risk factors alone are unlikely to accurately estimate CVD risk in RA and SLE. Indeed, authors of recent studies have reported that such risk scores (e.g., Framingham) underestimate CVD risk by twofold in patients with RA.[176] The SCORE, QRISK II, and Reynolds CVD risk calculators also underestimate future CV events in patients with RA, except for those in the highest risk classes.[174,176,177] In the latest European Society of Cardiology guidelines for CVD prevention,[178] immunologic diseases like RA were for the first time mentioned and categorized as a CV risk factor and have similarly been included in the latest version of the British CV risk calculator, the QRISK II.[179] The European League Against Rheumatism (EULAR) recognizes that patients with inflammatory joint diseases have increased risk for CVD and made recommendations for management of CV risk factors based largely on expert consensus.[174] The EULAR task force group was

well aware of the lack of evidence and made a conservative recommendation for a multiplication factor of 1.5 to the calculated CVD risk by SCORE, if the patient with RA had two or more of the following factors: disease duration greater than 10 years, RF/ACPA positivity, or extraarticular manifestations. Corrales and colleagues[180] report that utilizing the 1.5 multiplication factor reclassifies only 0.03% of the patients into more appropriate CVD risk classes, but even then patients at high risk and those with asymptomatic carotid atherosclerosis were not adequately identified. Thus the multiplication factor does not fully adjust for the increased CVD risk in RA. Further development of accurate CVD risk assessment tools for RA and SLE are needed to allow incorporation of inflammatory and disease-related factors that may help predict CVD in these patients, such as the RA-specific risk calculator that is currently being developed by the A TransAtlantic Cardiovascular risk Calculator for Rheumatoid Arthritis (ATACC-RA) consortium.[80,176-178,181-187]

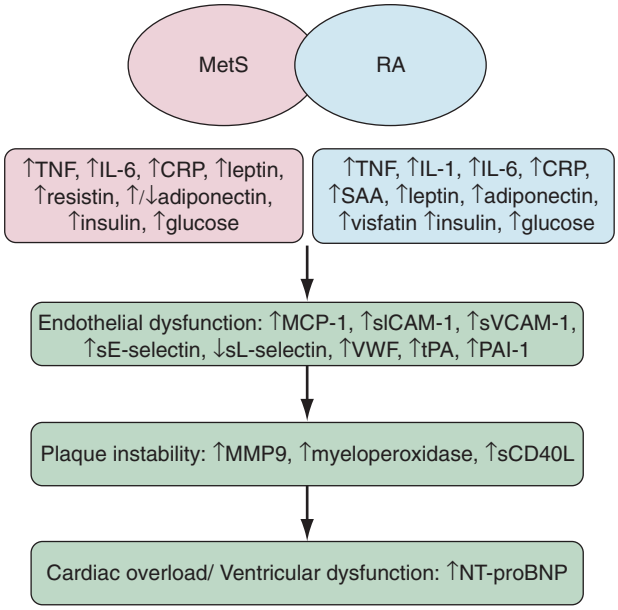

**Figure 36-10** Key soluble biomarkers that are associated with different stages of the atherosclerotic pathway in the metabolic syndrome and rheumatoid arthritis (RA). CRP, C-reactive protein; IL, interleukin; MCP, monocyte chemotactic protein; MetS, metabolic syndrome; MMP, matrix metalloproteinase; NT-proBNP, N-terminal pro–brain natriuretic peptide; PAI-1, plasminogen activator inhibitor-1; SAA, serum amyloid A; sICAM, soluble intercellular adhesion molecule; sVCAM, soluble vascular cell adhesion molecule; TNF, tumor necrosis factor; tPA, tissue plasminogen activator; VWF, von Willebrand factor. *(From Kozera L, Andrews J, Morgan AW: Cardiovascular risk and rheumatoid arthritis-the next step: differentiating true soluble biomarkers of cardiovascular risk from surrogate measures of inflammation.* Rheumatology *50:1944–1954, 2011. Permission to reprint from Oxford University Press.)*

## CONNECTION TO THE CLINIC

### Risk Scores and Risk Markers: Biomarkers and Tests for Subclinical Disease

One reason for underestimation of CVD risk in persons with RA may be the high frequency of asymptomatic atherosclerosis,[181-184] which is easily visualized upon ultrasound of the carotid arteries. In addition, carotid artery plaques in patients with RA have been shown to be predictors of a future acute coronary syndrome.[185] Moreover, in the recent European guidelines on CVD prevention,[178] the presence of carotid artery plaques is considered a CVD equivalent, which suggests that including ultrasound of carotid arteries in the CVD risk evaluation would increase the proportion of correct risk stratification.[183,186,187] Other tests for subclinical disease that might be useful for assessing CVD risk in patients with RA include aortic pulse wave velocity and lipoprotein(a).[188] Soluble biomarkers are also appealing because they are typically less costly and have more widespread availability.[68] However, they also may be more difficult to interpret in patients with rheumatic disease because of their dual association with CVD and rheumatic disease (Figure 36-10).[68]

These assessments currently may not be feasible in rheumatology outpatient clinics, but they will provide a great advantage if they are included as a risk evaluation tool in the future. In conclusion, available CVD risk calculators developed for the general population seriously underestimate CVD risk in patients with RA but currently represent the best utility for CVD risk evaluation in these patients.

### Translating Knowledge into Clinical Practice

Despite the large and growing body of knowledge showing increased risk of CVD in persons with RA and other rheumatic diseases even when controlling for traditional CV risk factors,[33,176] little translation into clinical care has occurred. Inflammation and immune mechanisms underlie the atherosclerotic process.[189] Because traditional risk factors alone do not explain the elevated CVD risk in patients with rheumatic diseases, addressing control of inflammation is essential to decrease the CVD risk.[190]

Thus close collaboration between the rheumatologist and the cardiologist is vital.[191-193] Not only does the rheumatologic condition need to be treated aggressively to decrease the inflammatory burden, but the traditional CV risk factors must be identified and appropriately treated. Specialized CV clinics that specifically address the needs of rheumatologic patients allow these patients to be followed up in a more rigorous fashion, with more uniform evaluation and longitudinal follow-up. Examples of such clinics include the Preventive Cardio-Rheuma clinic at the Department of Rheumatology at Diakonhjemmet Hospital in Norway and the Cardio-Rheum clinic at the Division of Cardiovascular Diseases at Mayo Clinic in Rochester, Minnesota. Both models represent deep and ongoing collaborations between the clinical disciplines of rheumatology and preventive cardiology. Integral to both models are (1) extensive patient and provider education regarding CVD risk in the unique setting of autoimmune diseases such as RA; (2) comprehensive CVD risk assessment including history, physical examination, and use of relevant risk assessment scores, as well as noninvasive and (when indicated) invasive measurement techniques; and (3) development and monitoring of an aggressive plan for CVD risk reduction, considering not only traditional CVD risks but also tight control of systemic inflammation and RA disease management. Each program

also includes a clinical research component aimed at continually evaluating and improving the preventive care paradigms.

## Managing CVD Risk in Patients with Rheumatic Disease

Both in Europe and in the United States, patients with RA are significantly less likely to receive CVD preventive measures compared with the general population.[194] A study showed that despite receiving similar treatment, patients with RA who had an MI experienced worse long-term outcomes than did patients with an MI who did not have RA.[23] This deficiency in CVD risk management is amply confirmed in an investigation of CV risk factor control in 836 patients with RA by Primdahl and colleagues.[195] Among the most striking observations is that in the 644 patients without established CVD or diabetes mellitus, inadequate blood pressure and lipid control was documented in 36% and 55% of the participants, respectively. Findings from a preventive cardio-rheuma clinic revealed that 63% of the patients referred were in need of CVD preventive medical intervention.[184]

Compounding the uncertainties surrounding management of CVD risk, no evidence is available regarding CVD preventive treatment effects in patients with RA. To date, there is a lack of published prospective RCTs in RA comparing either different primary prevention strategies (e.g., lipid-lowering or anti-hypertensive medications) or the effects of the different anti-rheumatic drugs using CVD outcomes as the primary endpoint. Such trials require a high number of patients monitored for lengthy periods and have high cost. Promising results from a post hoc analysis of two large statin trials with CVD endpoints showed that effects on lipid reduction and CVD events by statins were comparable in patients with and without inflammatory joint diseases, including RA.[196] A large RCT regarding statin versus placebo (Trial of Atorvastatin for the Primary Prevention of CVD Events in patients with Rheumatoid Arthritis [TRACE RA], including >3000 patients with RA) was recently prematurely terminated because of a low incidence of the primary CVD endpoint and because power was inadequate to be able to reach a clear conclusion.

An important CV risk factor in the general population is lipid levels; however, lipid levels appear to be less important for patients with inflammatory joint diseases.[80] However, meta-analyses of RCTs have shown that patients in the general population benefit from lipid-lowering treatment regardless of baseline lipid levels.[197] Clinical experience regarding use of CVD preventive medications in inflammatory joint diseases is scarce. Experience from a preventive cardio-rheumatology clinic for patients with inflammatory joint diseases revealed that lipid targets were attained using fewer than three consultations in 90% of the patients without serious adverse events.[184] These results indicate that treating patients who have RA with statins and achieving recommended lipid goals is safe. Prospective, longitudinal data are needed to demonstrate whether patients with RA need to achieve the same low lipid targets as persons without RA, or if a relatively smaller or larger reduction in lipids will result in the same CVD protection as in persons without RA.

Modern RA therapy and the multiple comorbidities lead to polypharmacy, thus increasing the possibility of drug to drug interactions with CVD preventive medications such as statins. Interaction between anti-rheumatic treatments as NSAIDs and synthetic or biologic DMARDs with CVD preventive medications is also an area of uncertainty. The influence of statins on clinical response and B cell depletion after rituximab treatment in persons with RA is inconclusive.[198,199] An increased CVD risk associated with NSAID use is recognized in the general population,[120,200] but in a recent Danish nationwide study, the CVD risk associated with use of NSAIDs in persons with RA was modest and significantly lower than in persons without RA.[201] Furthermore, NSAIDs interfere with the thrombocyte inhibitory effect of aspirin, which complicates secondary CVD prevention.[202] Observational studies have provided indications that use of synthetic and biologic DMARDs is associated with reduced CVD risk in persons with RA.[122,124] However, it is unknown whether this effect is related to the reduction in inflammation opposing the increased levels of atherogenic lipids that occur with biologic DMARDs and improvement of HDL function.[203] Studies to clarify these issues are needed.

CVD prevention in patients with RA is fraught with concerns of drug- and disease-related complexities. Therapies of rheumatic conditions have evolved enormously in the past two decades, as have CVD prevention strategies. The available literature suggests substantial underuse of CVD preventive pharmacotherapy in the general population.[204,205] According to the latest DYSlipidemia International Study (DYSIS) report, more than half of all patients were not reaching their LDL treatment goal in general practice.[204] These findings are also supported by the Eurospire III report, which indicates that clinical implementation of secondary prevention treatments remains suboptimal.[205]

Efforts to address the high CVD risk in patients with rheumatic disease should be a focus in the cardiology community and among rheumatologists. It is hoped that such a focus will result in more patients with RA being evaluated for CVD risk and the institution of preventive measures when necessary.

## Patient Awareness of Cardiovascular Disease Risk

Communicating future risk and the need for preventive treatment is one of the most challenging aspects of the patient/health professional interaction. Awareness of patients about their CVD risk is important for successful implementation of preventive strategies related to lifestyle modifiable CV risk factors.[206] Although such programs for assessing CVD risk in persons with RA have been developed, it will take a great effort to fully disseminate them. These strategies include education of health care professionals, written material, and online and group education of patients and their families. Even starting with simple information and brochures as a precursor to implementing a full education program is a step forward. It is of the utmost importance for patients with rheumatic diseases to understand that effective CVD risk management comprises not only adequate treatment of conventional CV risk factors but also tight control of the rheumatic disease activity.

## FUTURE DIRECTIONS

CVD remains a major problem for people with systemic inflammatory diseases. Systemic inflammation and its interplay with traditional and nontraditional CV risk factors appear to have a major role. Future work should focus on further delineating the underlying biologic mechanisms involved, developing and evaluating risk assessment tools and biomarkers, and prevention and treatment strategies specific to rheumatic disease populations. Optimal control of traditional risk factors is imperative but insufficient to reduce CVD risk for people with rheumatic diseases. Tight control of systemic inflammation will be required for optimal results.

CHAPTER 37

# Cancer Risk in Rheumatic Diseases

Eric L. Matteson

**KEY POINTS**

- Risk of malignancy, especially lymphoproliferative malignancy, is increased in autoimmune rheumatic diseases.
- The occurrence of cancer in patients with rheumatic diseases adversely affects quality of life and life expectancy compared with the general population.
- This risk is related to the pathobiology of the underlying rheumatic disease, including the inflammatory burden, immunologic defects such as overexpression of *Bcl*-2 oncogenes, traditional risk factors such as smoking, and, in some cases, associated viral infection.
- Several of the immunomodulatory treatments used in the management of autoimmune disease, especially chemotherapeutic agents, are associated with an increased risk of cancer.
- The decision to use immunomodulating therapies in patients with rheumatic disease must take into account host and environmental risk factors for cancer. Effective screening and monitoring strategies can markedly reduce the risk of cancer in these patients.

Systemic rheumatic diseases have been associated with an increased risk of development of malignancy. This increased risk is the result of fundamental underlying immunologic effects of autoimmunity on cancer risk and on the risk of cancers associated with drug treatments for rheumatic diseases.

Accelerated growth of cancer cells in immunodeficient mice and increased risk of cancer in heavily immunosuppressed transplant patients have shaped the perception of the immune system as a potent barrier against neoplasms.[1,2] It might be expected that immunosuppressive treatment would inevitably result in effects favoring malignant cell growth. However, emerging evidence supports the seemingly paradoxical notion, perhaps formulated first by Rudolph Virchow in 1863, that inflammation is a critical component of cancer initiation and progression, and that reduction of systemic inflammation may reduce cancer risk in these conditions.[3]

Assessment of cancer risk in rheumatic diseases must be weighed against the lifetime risk of developing cancer, which is approximately 20% in Western Europe and North America, with 5% of the general population having current cancer or a history of cancer.[4] Breast cancer will develop in approximately 1 in 10 women , prostate cancer will develop in as many as 1 in 8 men, colorectal cancer in 1 in 25, lung cancer in 1 in 40, and approximately 1 in 100 will develop lymphoma or other lymphoproliferative malignancy.[4]

The combination of increased risk for some and decreased risk for other types of cancers in different rheumatic diseases may result in a neutral effect for malignancies in general, emphasizing why, from a clinical standpoint, it is important to identify risks pertaining to specific cancers, which may be uncommon. The statistical approach for capturing differences in sparse event data, particularly when malignancy is not a prespecified study outcome, and assumptions of proportional hazards models and stable frequencies of events during a period of time for a nonlinear risk such as cancer can lead to major errors in interpretation.

## MALIGNANCY IN AUTOIMMUNE RHEUMATIC DISEASES

Several rheumatic diseases, particularly lymphoproliferative disorders, appear to be associated with increased risk of malignancy. A list of rheumatic diseases that have been associated with malignancy is provided in Table 37-1. A global assessment of susceptibility to Hodgkin's lymphoma that used population-based linked registry data from Sweden and Denmark identified significantly increased risks of Hodgkin's lymphoma associated with a personal history of autoimmune disorders, including rheumatoid arthritis (RA; odds ratio [OR], 2.7; 95% confidence interval [CI], 1.9 to 4.0), systemic lupus erythematosus (OR, 5.8; 95% CI, 2.2 to 15.1), sarcoidosis (OR, 14.1; 95% CI, 5.4 to 36.8), and immune thrombocytopenic purpura (OR, ∞; $P = 0.022$).[5] A statistically significant increase in the risk of Hodgkin's lymphoma was associated with family histories of sarcoidosis (OR, 1.8; 95% CI, 1.01 to 3.1) and ulcerative colitis (OR, 1.6; 95% CI, 1.02 to 2.6).[5]

The occurrence of cancer has a profound effect on the already compromised quality of life of patients with rheumatic diseases and may affect survivorship and influence treatment decisions. A population-based study of cancer survival in patients with inflammatory arthritis from Great Britain suggests decreased survival compared with the general population.[6] Survivorship related to the occurrence of cancer in this population was unrelated to disease-modifying anti-rheumatic drug (DMARD) exposure.[6]

**TABLE 37-1** Rheumatic Diseases Associated with Malignancy

| Connective Tissue Disease | Malignancy | Associated Factors | Clinical Alert |
|---|---|---|---|
| Sjögren's syndrome | Lymphoproliferative disorders | Glandular features: lymphadenopathy, parotid or salivary enlargement<br>Extraglandular features: purpura, vasculitis, splenomegaly, lymphopenia, low C4, cryoglobulins | Clues to progression from pseudolymphoma to lymphoma include worsening of clinical features, disappearance of rheumatoid factor, and decline of IgM |
| Rheumatoid arthritis | Lymphoproliferative disorders | Presence of paraproteinemia, greater disease severity, longer disease duration, immunosuppression, Felty's syndrome | Rapidly progressive; refractory flare in long-standing rheumatoid disease may suggest an underlying malignancy |
| Systemic lupus erythematosus (SLE) | Lymphoproliferative disorders | — | Non-Hodgkin's lymphoma should be considered in SLE patients who develop adenopathy or masses; lymphoma of the spleen is another cause of splenic enlargement in SLE |
| Systemic sclerosis (scleroderma) | Alveolar cell carcinoma<br>Nonmelanoma skin cancer<br>Adenocarcinoma of the esophagus | Pulmonary fibrosis, interstitial lung disease<br>Areas of scleroderma and fibrosis in the skin<br>Barrett's metaplasia | Annual chest radiograph after fibrosis is detected<br>Change in skin features or poorly healing lesions should be evaluated<br>If indicated, esophagoscopy and biopsy of distal esophageal constricting lesions |
| Dermatomyositis | Ovarian, lung, and gastric cancers in Western populations; nasopharyngeal carcinoma in Asian populations | Older age, normal creatinine kinase levels, presence of cutaneous vasculitis; less likely in setting of myositis-specific antibodies | Malignancy evaluation needs to be tailored to individual patient's age, symptoms, and signs |

## RHEUMATOID ARTHRITIS

### KEY POINTS

**Rheumatoid arthritis is associated with a greater than twofold increased risk of lymphoma. This risk is higher in patients with high disease activity and with more severe disease, including extra-articular involvement.**

**The risk of solid malignancies is variable, with an increased risk of lung cancer and likely decreased risk of colorectal cancer, breast cancer, and cancers of the urogenital tract in both men and women.**

A considerable body of evidence supports rheumatoid arthritis as a pathogenic factor in the development of lymphoma. A standardized incidence ratio (SIR) of 2.4 for lymphoma was described in a population of more than 20,000 Danish patients, as was an increased risk of 1.8 (95% CI 1.5-2.2) in 19,591 U.S. patients.[7,8]

With use of a different approach, a pooled SIR of 3.9 for lymphoma was found by using a random effects model in a meta-analysis.[9] Studies that used other methods have found ORs of 1.3 to 1.5 for lymphoma in case-control studies.[10]

Patients with RA may be at higher risk for non-Hodgkin's lymphoma, especially diffuse large B cell type.[9] Large B cell lymphomas represent as much as two-thirds of non-Hodgkin's lymphomas in patients with RA[5,6]—approximately twice the rate of diffuse large B cell lymphoma as a proportion of overall non-Hodgkin's lymphoma in the general population. The immunophenotype, grade, and histology of lymphomas in patients with RA are not different from the general population.

In many studies, the risk of cancer is particularly increased early in the disease course, and cancer risk appears to be greater in patients who have persistently high disease activity, high cumulative disease activity, and more severe disease, and in those who have positive rheumatoid factor (SIR, 3.6; 95% CI, 1.3 to 7.8).[10,11] The unadjusted OR for average disease activity, comparing highest versus lowest quartile, was 71.3 (95% CI, 24.1 to 211.4), and the OR for cumulative disease activity of the tenth decile versus the first decile was 61.6 (95% CI, 21.0 to 181.0) in a case-control registry study from Sweden.[11]

Extraarticular disease of RA, particularly Felty's syndrome and Sjögren's syndrome, confers a further increased risk of non-Hodgkin's lymphoma; one study of 906 men with RA revealed a twofold increase in total cancer incidence among patients with RA who have Felty's syndrome.[12] Large granular T cell leukemia (T-LGL) may, rarely, occur in association with RA.[13] T-LGL in RA usually is chronic and in rare cases becomes aggressive.

Whether patients with RA are at higher risk for lymphoproliferative disorders other than lymphoma is unclear. A meta-analysis of 21 publications from 1990 to 2007 summarized the risk of malignancy in patients with RA.[14] The risk of lymphoma was increased approximately twofold (SIR, 2.08; 95% CI, 1.8 to 2.39), with greater risks of Hodgkin's and non-Hodgkin's lymphoma. The risk of lung cancer was increased, with an SIR of 1.63 (95% CI, 1.43 to 1.87). The risk of colorectal cancer was decreased (SIR, 0.77; 95% CI, 0.65 to 0.90), as was the risk of breast cancer (SIR, 0.84; 95% CI, 0.79 to 0.90). The overall SIR for malignancy was slightly increased, at 1.05 (95% CI, 1.01 to 1.09). The overall increased risk of cancer in patients with RA was largely caused by the increased risk of lymphoproliferative cancers.

The risk of lung cancer appears to be higher among patients with RA. U.S. veterans with RA were 43% more likely (OR, 1.43) to develop lung cancer compared with patients without RA, after adjustments were made for age, gender, race, and tobacco and asbestos exposure. The risk for lung cancer in British patients on nonbiologic DMARDs was found to be higher as well (SIR, 2.39; 95% CI, 1.79, 5.07.[15,16]

Details from the study of 42,262 patients hospitalized with RA from 1980 to 2004 indexed to the Swedish National Cancer Registry found that SIRs for Hodgkin's and non-Hodgkin's lymphoma were increased for upper digestive tract cancers and for squamous cell skin cancer, and detected an excess of nonthyroid endocrine tumors in patients with RA.[17] Colon and rectal and endometrial cancers were less frequent in patients with RA. The decreased risk of colorectal cancer may be attributable to the use of long-term nonsteroidal anti-inflammatory agents in patients with RA.[18]

In summary, cancer is frequent in the general population and is at least as common among patients with RA. Following a diagnosis of rheumatoid arthritis at the typical age of 55 years, one in five patients will be diagnosed with cancer; however, in the great majority of patients, the cancer cannot be linked to RA or to its treatment but rather reflects the background cancer risk.

## SYSTEMIC LUPUS ERYTHEMATOSUS

**KEY POINTS**

**The risk of lymphoma is at least twofold increased in systemic lupus erythematosus (SLE).**

**Risks of solid malignancy, including lung, thyroid, kidney, and skin cancers, are increased overall in SLE, although rates of cervix and prostate cancers appear to be somewhat lower. Breast cancer risk has been reported to be increased in some studies and decreased in others.**

The risk of at least certain malignancies appears to be increased in patients with SLE. Overall SIR ranges from 1.1 to 2.6,[19] with the most increased risk that of lymphomas (SIR, 3.57 for non-Hodgkin's lymphoma and 2.35 for Hodgkin's disease).[19,20] The risk is especially high for diffuse large B cell lymphoma, often of aggressive subtypes.[21,22]

A large multicenter (23 centers) international cohort of 9547 patients with an average follow-up of 8 years confirmed an increased risk of cancer in patients with SLE.[20] For all cancers combined, the SIR estimate was 1.15 (95% CI, 1.05 to 1.27); for all hematologic malignancies, it was 2.75 (95% CI, 2.13 to 3.49); and for non-Hodgkin's lymphoma, it was 3.65 (95% CI, 2.63 to 4.93). The data also suggest increased risks of lung cancer (SIR, 1.37; 95% CI, 1.05 to 1.76) and hepatobiliary cancer (SIR, 2.60; 95% CI, 1.25 to 4.78).[20]

Patients with SLE in a California statewide patient hospital discharge database from 1991 to 2001 were followed up by using cancer registry data to compare observed versus expected numbers of cancers based on age, sex, and specific incidence rates in the California population.[23] A total of 30,478 SLE patients were observed for 157,969 person-years. There were a total of 1273 cancers for an overall significantly increased cancer risk (SIR, 1.14; 95% CI, 1.07 to 1.20). Patients with SLE had higher risks of vagina/vulva (SIR, 3.27; 95% CI, 2.41 to 4.31) and liver cancers (SIR, 2.70; 95% CI, 1.54 to 4.24). Elevated risks of lung, kidney, and thyroid cancers and hematopoietic malignancies were also observed, with lower rates of screenable cancers, including breast cancer, cervix cancer, and prostate cancer. Drug effects were not assessed.[23]

Other studies have reported possibly increased risk of malignancies other than lymphoproliferative cancers in SLE. Patients may be at slightly higher risk of thyroid cancer.[24] An increased risk of squamous cell skin cancer was found in 238 patients with SLE.[25] The risk of breast cancer may be increased by approximately 1.5-fold to twofold compared with the general population, even after consideration of age, parity, family history, and exogenous estrogens.[19,26] The risk of abnormal Pap smears and cervical dysplasia appears to be higher in women with SLE than in those without, although the risk of invasive cervical cancer is not increased.[20]

The origin of any risk of the development of malignant disorders in SLE remains unclear, although it does not appear to be associated with the use of immunosuppressive or cytotoxic agents; most cohorts are too small to allow for detection of a statistically meaningful risk increase in rare events during short periods of observation. Race and ethnicity have not been identified as major factors in cancer risk in SLE.[27] Antimalarial drug use does not appear to affect the relative risk (RR) of malignancy, as was postulated in early studies.[28]

Risk factors for the development of hematologic malignancies may relate to inflammatory burden and disease activity, immunologic defects and overexpression of *Bcl-2* oncogenes, and viruses, especially Epstein-Barr virus (EBV).[29] A nested case-control study that included 6438 patients with SLE linked to the national cancer registry in Sweden found that leukopenia, independent of immunosuppressive treatment, was a risk factor for these leukemias. Bone marrow investigation was suggested for SLE patients with long-standing leukopenia and anemia.[30] Disease characteristics predisposing to non-Hodgkin's lymphoma include longer disease duration and increased disease activity with moderately severe end-organ damage.[31]

Women with SLE, likely out of concern for treatment side effects and effects of pregnancy on disease control, are less often exposed to oral contraceptives and are more likely to be nulliparous, which may affect their malignancy risk. On the other hand, the possible increase in breast cancer risk suggests that other, poorly understood factors may increase this risk in women with SLE, whereas at least one study suggests that patients with SLE are less likely than healthy women to undergo breast cancer screening.[32] Patients with SLE also appear to be less likely to undergo routine Pap testing. Increased prevalence of human papillomavirus infection and immunosuppression have been implicated in the apparent increase in prevalence of abnormal Pap smears and cervical dysplasia in patients with SLE.[33]

Women with SLE may be at higher risk of lung cancer, for which smoking is a predictor.[29] Similar to RA, smoking is a risk factor for both SLE and lung cancer, reflecting a complex interplay of disease susceptibility factors.

## SYSTEMIC SCLEROSIS (SCLERODERMA)

**KEY POINTS**

- Risks of lymphoma, skin cancer, and lung cancer are markedly increased in scleroderma.
- Scleroderma-related risk factors for malignancy include esophageal disease related to Barrett's esophagus and lung cancer related to pulmonary fibrosis.

The risk of malignancy in patients with scleroderma appears to be increased in most reviews and reports, although at least one population-based study failed to detect increased risk.[34,35] Generally, estimates of malignancy risk in scleroderma range from SIRs of 1.5 to 5.1, compared with the general population.[36,37] The highest SIRs for individual cancers are for lung cancer, with an incidence ratio of as high as 7.8, and non-Hodgkin's lymphoma, with an incidence rate ratio (IRR) of 9.6.

A population-based disease registry and cancer registry retrospective cohort linkage study from Sweden following up patients from 1965 to 1983 revealed an SIR of 1.5 for overall cancer, with the highest rates for lung cancer (SIR, 4.9), skin cancer (SIR, 4.2), hepatoma (SIR, 3.3), and hematopoietic malignancies (SIR, 2.3).[36] A cohort study of patients followed up from 1987 to 2002 revealed a similar magnitude of increased overall risk of malignancy (SIR, 1.55) with the observation of markedly increased risks of oropharyngeal cancer (SIR, 9.63; 95% CI, 2.97 to 16.3) and esophageal cancer (SIR, 15.9; 95% CI, 4.2 to 27.6).[36] Esophageal disease associated with systemic sclerosis is the likely reason for the increased incidence of Barrett's esophagus, which has been reported in 12.7% of patients with scleroderma.[37]

A high rate of abnormal Pap tests in women with onset of scleroderma before the age of 50 years has been reported, with a lifetime prevalence by self-report of 25.4% (95% CI, 20.9 to 30.4) compared with a self-reported prevalence of abnormal Pap tests in the general Canadian population of 13.8% (95% CI, 11.6 to 16.4). A significant relationship was found between self-reported abnormal Pap tests and diffuse disease and younger age at disease onset.[38]

Lung cancer has been reported to account for as many as 30% of all cancers in patients with scleroderma; it is thought to be related to fibrosis. The association with smoking is uncertain and studies are contradictory, with some reporting a link and others failing to find a link to smoking.[35,36,39]

The mechanisms of malignancy in scleroderma are largely unexplored. Risk factors for development of malignancy in patients with scleroderma may be related to inflammation and fibrosis of affected organs. The link to smoking is controversial.[35,39] As in some other autoimmune rheumatic diseases, the risk appears higher early in the disease, and patients who are older at the time of diagnosis may be at higher risk as well.[36,40] It is not certain whether the presence of scleroderma-specific antibodies, including topoisomerase I (Scl-70) and RNA polymerase I/III autoantibody, defines an increased risk for development of cancer in these patients.[34,40,41] Some patients with scleroderma harbor autoantibodies to RPC1, an RNA polymerase subunit encoded by the *POLR3A* gene that may drive both cancer and the disease.[41] In contrast to systemic sclerosis, localized scleroderma, including morphea and linear scleroderma, has not been associated with increased risk of cancer.[42]

## IDIOPATHIC INFLAMMATORY MYOPATHY

**KEY POINTS**

- The risk of cancer in patients with idiopathic inflammatory myopathies is approximately five to seven times higher than in the general population.
- Malignancy is strongly associated with dermatomyositis and, if present, is often detectable at disease outset.
- The most common malignancies in inflammatory myositis are adenocarcinomas.
- Suspicion for cancer should be high, especially in patients with active muscle and skin inflammation but normal creatine kinase levels, age older than 50 years, and periungual erythema.

Both dermatomyositis and polymyositis occurring in adults have been associated with malignancies. The link to malignancy in newly diagnosed patients with dermatomyositis is strongest, although in neither condition is the origin of the association well understood. The association between malignancy and polymyositis and inclusion body myositis is less strong.

Assessment of risk is complicated by the temporal relationship between the development of malignancy and cancer. In particular, some cancers predate the onset of inflammatory myopathy, so that the inflammatory myopathy can be better considered a paraneoplastic syndrome (see Chapters 85 and 123); it is also likely that the presence of inflammatory myopathies represents a risk factor for the subsequent development of malignancy.[43]

The incidence of cancer in patients with inflammatory myositis is approximately five to seven times higher than in the general population.[44] The prevalence of malignancy is approximately 25%; cancers are reported more frequently in dermatomyositis, occurring in 6% to 60% of patients, and in 0% to 28% of patients with polymyositis.[45]

In most studies, cancers manifest within 2 years before or after the initial diagnosis of inflammatory myopathy.[46,47] Inflammatory myopathies may initially manifest with the recurrence of a previously diagnosed cancer. A previously diagnosed but inactive inflammatory myopathy may become reactivated with occurrence of a cancer, supporting the hypothesis of autoantigens as drivers of the inflammatory disease.

The strength of the association between malignancy and inflammatory myositis varies. One study done at the Mayo Clinic failed to reveal an increased risk of malignancy in patients with inflammatory myopathy, and a more recent registry study from Sweden of 788 patients diagnosed with dermatomyositis or polymyositis between 1963 and 1987

revealed that 15% of 392 patients with dermatomyositis had cancer diagnosed concurrently with or after the diagnosis of dermatomyositis, with a relative risk of cancer of 2.4 (95% CI, 1.6 to 3.6) for males and 3.4 (95% CI, 2.4 to 4.7) for females.[43,46] Of 396 patients with polymyositis, 9% had cancer at or after the time of diagnosis of polymyositis, with the RR of 1.8 for development of cancer (95% CI, 1.1 to 2.7) in males and 1.7 (95% CI, 1.0 to 2.5) in females.

A population-based retrospective cohort study from Victoria, Australia, of 537 patients with biopsy-proven dermatomyositis and polymyositis reported an RR for malignancy in dermatomyositis compared with polymyositis of 2.4 (95% CI, 1.3 to 4.2), with a higher SIR for dermatomyositis than polymyositis (6.2 vs. 2).[47] Finally, ORs for association of cancer with dermatomyositis from a large meta-analysis were reported to be 4.4, and for polymyositis, 2.1.[48]

A wide range of malignancies are associated with dermatomyositis and polymyositis. The most common malignancies in populations of Northern European descent are adenocarcinomas of the cervix, lungs, ovaries, pancreas, bladder, and stomach, which account for more than two-thirds of these cancers.[43,44,48] In patients from Southeast Asia, a higher proportion of nasopharyngeal cancers are found, followed by lung cancer.[49]

The association of cancer is less well understood for more unusual forms of inflammatory myopathies. Amyopathic dermatomyositis, a rare form of dermatomyositis with typical cutaneous but no muscle involvement, can be associated with the development of cancer, but the frequency of this condition is low, so that no stable estimates of cancer risk are available.[50] Inclusion body myositis has not been well studied for the same reasons, although the overall risk of cancer of 2.4 suggests a possible link.[47]

It is likely that relevant antigens are expressed in the underlying tumor and affected muscle. Myositis-specific antigens develop during the process of regeneration in patients who have myositis; these are the same antigens expressed in some cancers known to be associated with the development of inflammatory myopathies.[51] This relationship is supported by the finding that antibodies to nuclear matrix protein NXP-2 or transcription intermediary factor 1γ are present in most (83%) patients with cancer-associated dermatomyositis.[52] A link between malignancy and inflammatory myositis is further supported by observations that in many cases myositis improves after removal of the malignancy.[53]

Clinical disease characteristics that may portend higher malignancy risk include active inflammatory disease with normal serum levels of creatine kinase, distal extremity weakness, pharyngeal and diaphragmatic involvement, and leukocytoclastic vasculitis.[54,55] In one study of 92 patients, other independent risk factors for the development of cancer in patients who have dermatomyositis included age at diagnosis older than 52 years (hazard ratio [HR], 7.24; 95% CI, 2.35 to 22.41), rapid onset of skin and/or muscle symptoms (HR, 3.11; 95% CI, 1.07 to 9.02), periungual erythema (HR, 3.93; 95% CI, 1.16 to 13.24), low baseline level of complement factor C4 (HR, 2.74; 95% CI, 1.11 to 6.75), and, possibly, topoisomerase I.[56,57] A low baseline lymphocyte count was a protective factor for malignancy (HR, 0.33; 95% CI, 0.14 to 0.80), although the number of assessable patients was small.[56]

## SJÖGREN'S SYNDROME

**KEY POINTS**

**The risk of lymphoproliferative cancers, especially various types of lymphoma, is at least sixfold increased in patients with primary Sjögren's syndrome.**

**Immunologic perturbations, including *p53* mutations and B cell activation, as well as *Helicobacter pylori*, are likely predisposing risk factors.**

Patients with primary Sjögren's syndrome are at increased risk of lymphoproliferative diseases. The overall cancer risk is increased compared with the general population (pooled RR, 1.53; 95% CI, 1.17 to1.88).[57] The relative risk for the development of lymphoproliferative disorders in these patients ranges from 6 to 44 in individual studies, and a meta-analysis of cohort studies reported a pooled SIR of 18.8.[58] Lymphoproliferative disorders eventually occur in between 4% and 10% of patients with primary Sjögren's syndrome, with a lifetime risk of non-Hodgkin's lymphoma of approximately 5%.[8,58-61]

In addition to non-Hodgkin's lymphoma, forms of lymphoproliferative disease seen in patients with Sjögren's syndrome include low-grade B cell lymphoma and diffuse large B cell lymphoma, including follicular center lymphoma. Less commonly seen lymphoproliferative diseases include lymphocytic leukemia, Waldenström's macroglobulinemia, and multiple myeloma.[60] Except for thyroid cancer (RR, 2.58), the risk of other cancers does not appear to be particularly high in patients with Sjögren's syndrome.[57,60,61] The development of lymphoma and malignancy in patients with Sjögren's syndrome does not appear to affect or cause mortality.[8,61]

The pathoetiology of lymphoproliferative diseases occurring in patients with Sjögren's syndrome is unclear. It is likely that the B cell activation characteristic of Sjögren's syndrome is a predisposing risk factor. Most lymphomas in Sjögren's syndrome appear to arise from lymphoepithelial sialadenitis or benign lymphoepithelial lesions, perhaps associated with *p53* mutations.[62] Infectious agents such as hepatitis C and Epstein-Barr virus have been implicated, although the nature of this relationship remains speculative. *Helicobacter pylori* is associated with MALT (mucosa-associated lymphoid tissue) lymphoma in Sjögren's syndrome.[63]

Appropriate evaluation in symptomatic patients should include diagnostic testing for *H. pylori* in this setting.[64] The link of cancer in Sjögren's syndrome to the proto-oncogene *Bcl-2* translocation is, as yet, not clearly defined but may be helpful for early detection of malignancy.[65,66]

## VASCULITIS

**KEY POINT**

**It is unclear whether the risk of cancer development is increased in vasculitis independent of drug treatment effects.**

Vasculitis as a paraneoplastic syndrome may be present in about 8% of patients with malignancy (see Chapter 123).[67] Not as well studied is the risk of primary malignancy in

patients with vasculitis. Most cases appear to be related to treatment, although one study that used the Danish Cancer Registry suggested an increased risk of nonmelanoma within 2 years of the vasculitis diagnosis in anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV) (granulomatosis with polyangiitis [GPA]) (OR, 4.0; 95% CI, 1.4 to 12).[68]

Current data do not support a link between ANCA-associated vasculitis (GPA) and malignancy as a trigger for vasculitis, or the vasculitis itself as a trigger for malignancy, independent of treatment effects. However, data from several studies suggest a standardized incidence ratio of cancer in AAV of 1.6 to 2.0 compared with the general population and a possibly higher risk in GPA than in microscopic polyangiitis (MPA).[69]

The risk of malignancy among patients with giant cell arteritis was not increased in a population-based study of 204 patients with giant cell arteritis and 407 age- and sex-matched controls.[70]

## SERONEGATIVE SPONDYLOARTHRITIS

### KEY POINT

**The overall risk of cancer does not appear to be increased in seronegative spondyloarthropathies.**

The risk of cancer among patients with spondyloarthropathies is not as well studied as that of patients with RA and other connective tissue diseases. A cohort study from Canada of 665 patients with psoriatic arthritis revealed an SIR for all cancers of 0.98 (95% CI, 0.77 to 1.24) without evidence of increase in cancer type–specific SIR for hematologic, lung, or breast cancer.[71] A U.S.-based study of 2970 patients with psoriatic arthritis and 19,260 patients with RA found that overall malignancy incidence was similar at 0.56 per 100 person years for both diseases, and incidence rates were similar across malignancy subtypes.[72]

No overall increased risk of cancer has been noted among patients with ankylosing spondylitis, as was reported in a Swedish national cohort of patients with ankylosing spondylitis admitted to Swedish hospitals from 1965 to 1995, linked to the Swedish National Cancer Registry and Death Registry. These patients appear to not have increased risk of malignant lymphoma.[73,74] A population-based cohort study of patients with ankylosing spondylitis from Australia suggests a prevalence of malignancy of 6.8%, which parallels baseline population prevalence rates reported in Western populations.[75] In contrast, an increased rate of cancer in Asians with ankylosing spondylitis was reported using national health insurance system data in Taiwan. Matching each of 4133 patients with 4 comparators, the HR for all cancers was 1.38 (95% CI, 1.18 to 1.60).[76]

## CANCER RISKS ASSOCIATED WITH ANTI-RHEUMATIC DRUG THERAPIES

### KEY POINTS

**The effect of therapies used in the treatment of autoimmune rheumatic diseases on cancer can be difficult to distinguish from the underlying risk intrinsic to the diseases.**

**Nonsteroidal anti-inflammatory drugs and glucocorticosteroid have not been associated with increased risk of cancer.**

**The risk of cancer with chemotherapeutic drugs is greatest in patients who have had the highest cumulative exposure to these agents.**

**Chronic active inflammation is related to increased risk of lymphoma in RA. Effective management of the underlying disease may reduce this risk.**

Assessment of risk associated with both nonbiologic and biologic DMARDs is challenging because of the overall generally high burden of cancer in the population, the variable rheumatic disease–related cancer risk, and the potential risk of cancer associated with agents used to treat them. Disease severity may be a risk factor for developing cancer, introducing confounding or channeling bias if patients with severe disease are treated more intensively with immunomodulatory agents. The sequential and combined use of immunomodulatory agents further complicates the assessment of risk related to individual agents. A further concern, as with all immunosuppressive drugs, is the oncogenic potential of immunosuppressive therapies in patients who have a pre-existent or concurrent cancer, and whether such patients should be treated with DMARDs, and if so, which DMARDs should be given. Major guidelines for management of rheumatic diseases lack recommendations for DMARD use in patients with pre-existing malignancies [77,78]

Nonsteroidal anti-inflammatory agents and glucocorticosteroids do not appear to be associated with increased risk of malignancy in patients with RA nor other rheumatic diseases.[79] In a large population-based cohort study from Sweden, a total duration of oral corticosteroid treatment of less than 2 years was not associated with lymphoma risk (OR, 0.87; 95% CI, 0.51 to 1.5), whereas treatment lasting longer than 2 years was associated with a lower lymphoma risk (OR, 0.43; 95% CI, 0.26 to 0.72).[80] The duration of RA at initiation of oral corticosteroids did not affect lymphoma risk. Whether this observed reduction in lymphoma risk may be due to decreased disease activity, is a generic effect of corticosteroids, or is specific to RA, is uncertain.[80]

## NONBIOLOGIC DISEASE-MODIFYING ANTI-RHEUMATIC DRUG THERAPY

### KEY POINTS

**The nonbiologic disease-modifying anti-rheumatic drugs (nb-DMARDs) gold, hydroxychloroquine, penicillamine, and sulfasalazine are not associated with an increased risk of cancer.**

**The risk of lymphoma, especially B cell lymphoma, may be increased with methotrexate. Some patients may experience regression with discontinuation of methotrexate.**

**Use of azathioprine is associated with increased risk of lymphoma, and alkylating agents are particularly associated with increased risk of several types of malignancies, including bladder and lung cancer and leukemia in patients treated with cyclophosphamide.**

The nb-DMARDs sulfasalazine, hydroxychloroquine, gold, and penicillamine do not appear to be associated with an increased risk of cancer. Radiation is no longer used for the treatment of rheumatic diseases and will not be further addressed. Although no increase in cancer occurrence has been reported, few data are available regarding the long-term risks of malignancies occurring with leflunomide.[81]

All of the anti-metabolites used in prevention of transplant rejection and treatment of cancer have tumorigenic potential and, in general, may, or do, confer an increased risk of malignancy. The risk of cancer is increased with chemotherapeutic nb-DMARDs, particularly cyclophosphamide, and the risk of certain cancers, particularly lymphoproliferative disorders, may be increased with the use of other nb-DMARDs, such as azathioprine, methotrexate, and cyclosporine, although data are relatively sparse. Data regarding cancer risk in rheumatic diseases in patients treated with mycophenolate mofetil are few, although cancers clearly do occur in patients treated with this drug.[82]

Overall risk for cancer in patients with RA treated with nb-DMARDs was found to be 28% higher compared with the general population in a review of 3771 patients from the British Society for Rheumatology Biologics Register.[16] The cancer risk appears to be greatest in patients who have had the highest cumulative exposure to DMARDs, compared with patients with less than 1 year of exposure (SIR, 4.82).[83] Exposure to azathioprine, cyclosporin or cyclophosphamide increased the relative risk for cancer 65% in the British study, although only 367 patients had taken one of these drugs.[16]

### Methotrexate

The overall malignancy risk attributable to methotrexate treatment in patients with rheumatic diseases does not appear to be increased, although numerous studies suggest that the risk of lymphoproliferative disease may be increased. This increase may be related to higher weekly doses, but not the cumulative dose of methotrexate.[84]

Most cases of methotrexate-associated lymphomas reported in the literature are B cell lymphomas, often with extranodal involvement.[85] Assays for EBV in one study revealed that 7 of 17 patients (41%) were positive.[85] Further evidence supporting a link between methotrexate use and the development of lymphoma comes from observations of spontaneous remission of B cell lymphoma in 8 of 50 cases, including 4 that were positive for EBV.[85] This suggests that methotrexate may potentiate persistent immunologic stimulation, clonal selection, and malignant transformation of B cells by direct oncogenic action, decreased apoptosis of infected B cells, and decreased natural killer cell activity.[85]

### Azathioprine

The use of azathioprine may be associated with increased risk of lymphoproliferative disorders. Studies from a Canadian azathioprine registry revealed increased rates of lymphoproliferative disorders in patients with RA compared with the general population (SIR, 8.05).[86] A study from Britain also revealed a markedly increased risk of development of lymphoma in RA patients treated with azathioprine, with an estimated 1 case of lymphoma per 1000 patient-years of azathioprine treatment.[87] Risk was highest in patients on higher daily doses of azathioprine of as much as 300 mg per day.

The risk of leukemia in patients with SLE treated with azathioprine has been generally reported as not increased, although one study reported an increase in risk.[88] In as many as 24 years of longitudinal follow-up, 5.4% of patients treated with azathioprine developed malignancies, none of which were lymphomas, compared with 6.7% of patients who had never received azathioprine, three of whom developed lymphoma.[88]

### Cyclosporine

Relatively few patients with rheumatic diseases treated with cyclosporine have been followed for protracted periods, making assessment of malignancy risk in these patients difficult. Similar to methotrexate, cyclosporine has been associated with the development of EBV-associated lymphomas in a few patients with rheumatoid arthritis.[89] A retrospective study aggregating experience from clinical trials of more than 1000 patients with RA treated with cyclosporine failed to demonstrate an increased risk of malignancy, at least beyond that seen with other DMARDs.[90]

### Alkylating Agents

The use of alkylating agents in patients with RA, systemic lupus erythematosus, and vasculitis has been associated with an increase in non-Hodgkin's lymphoma, leukemia, skin cancer, bladder cancer, and solid malignancies.[91,92,93] Considerably more experience with cyclophosphamide than chlorambucil has been documented in these diseases.

Cyclophosphamide use in rheumatic diseases is associated with an overall increased risk of developing malignancy of between 1.5 and 4.1, compared with control subjects. This risk is best studied in AAV (especially necrotizing GPA), in which risk is highest for bladder cancers (SIR, 4.8), leukemia (SIR, 5.7), and lymphoma (SIR, 4.2). Bladder cancer is a particular concern, and patients who have been treated with higher doses over longer periods and those who smoke appear to be at especially high risk.[92] Bladder cancer related to cyclophosphamide use may occur within 1 year of initiation of therapy and as long as 15 years or longer after discontinuation of cyclophosphamide treatment.[92]

Increased risk of hemorrhagic cystitis of the urinary bladder or development of bladder cancer is caused by cyclophosphamide metabolites, especially acrolein. For this reason, current recommendations are to attempt to restrict the use of cyclophosphamide to 6 months or less, and to use it only in life-threatening or organ-threatening disease. The risk of bladder cancer, although probably not the overall malignancy risk, may be less with the use of pulse intravenous cyclophosphamide than with daily oral administration. Some authors advocate concurrent administration of mesna, which inactivates acrolein in the urine. Mesna may be administered intravenously at the time of pulse cyclophosphamide dosing, or by mouth daily, although this is rarely done because of its disagreeable taste.

## BIOLOGIC THERAPEUTIC AGENTS

**KEY POINTS**

**The overall risk of cancer associated with biologics used in the treatment of RA does not appear to be markedly increased from baseline cancer risk in these patients.**

**The risk of skin cancer, especially nonmelanoma skin cancer, does appear to be somewhat increased by approximately 1.5-fold in patients treated with anti–tumor necrosis factor therapy.**

Biologic response modifiers target specific pathways involved in the pathogenesis of some rheumatic diseases such as RA and spondyloarthritis. The term *targeted* should not imply absolute selectivity between physiologic and pathologic processes with these drugs. It is speculative that the risk of malignancy with use of biologics therapy may be related to the specific biologic mechanisms of the drug. However, a review of 63 randomized clinical trials with 29,423 patients on abatacept, adalimumab, anakinra, certolizumab, etanercept, golimumab, infliximab, rituximab and tocilizumab for at least 6 months' duration did not find a significantly increased risk of malignancy.[94] An important aspect of all randomized clinical trials of biologics is the exclusion of patients with a history of cancer, sometimes excepting nonmelanoma skin cancer (NMSC).

### Anti–Tumor Necrosis Factor Agents

Since their introduction, anti–tumor necrosis factor (TNF) agents have been studied over a wide range of indications. The concern regarding cancer arises from animal models of TNF action, in vitro studies, and studies in humans that suggest that TNF is important in cancer initiation and promotion. Indeed, anti-TNF agents may even be beneficial for patients with cancers, although clinical evidence of such a benefit is lacking.[95] An interesting observation of regression of non–small cell lung cancer in a patient receiving anti-TNF therapy has been reported, which adds to the biologic plausibility of a connection between anti-TNF therapies and malignancy in individual patients who may have particular susceptibility.[96]

When comparing patients on anti-TNF agents with patients on nb-DMARDs, cancer does not occur more frequently,[97,98,99,100,] nor does lymphoma.[98-102] NMSC does not occur more frequently,[99,103,104] whereas melanoma may occur more frequently.[105] Table 37-2 contains a list of meta-analyses and cohort studies undertaken to explore anti-TNF treatment and solid cancers, lymphoma, NMSC, and melanoma in RA.

The possibly increased risk of cancer early after the start of anti-TNF therapy may be a factor in meta-analyses of randomized clinical trials, which have suggested a possibly increased risk of cancer in patients with RA treated with these agents. One meta-analysis of nine randomized clinical trials (RCTs) including infliximab and adalimumab found an OR of 2.4 for developing any malignancy for patients receiving infliximab or adalimumab compared with patients receiving placebo.[106] A meta-analysis of RCTs including 15,418 patients on anti-TNF agents and 7486 randomly assigned to comparators could not refute or verify that individual anti-TNF therapies affect the short-term clinical emergence of cancer.[107]

A pooled analysis of RCTs that used etanercept, infliximab, or adalimumab attempted to distinguish between the effects of recommended versus higher doses of anti-TNF on the development of malignancy, excluding NMSC. Exposure-adjusted analysis revealed ORs of 1.21 (95% CI, 0.79 to 4.28) and 3.04 (95% CI, 0.05 to 9.68) in patients treated with recommended and high doses of anti-TNF agents, respectively.[108]

Results of larger observational studies have not replicated the increased risk of malignancy observed with meta-analytical approaches. In the Swedish Biologics Registry, overall cancer risk was similar in anti-TNF–treated patients with rheumatoid arthritis compared with three different control cohorts.[97] In this database, no trend toward increased cancer incidence was noted with longer duration of TNF exposures. Studies from other databases, including the German and British Biologic Registries and North American cohort and administrative databases, have detected no significant safety signals with respect to overall cancer risk.[99,100,109,110]

Use of anti-TNF agents may be associated with an increased risk of NMSC. An OR for nonmelanoma skin cancer of 1.5 (95% CI, 1.2 to 1.8) was reported from the U.S. National Databank of Rheumatic Diseases.[109] A cohort study from this population suggested that the combination of TNF plus methotrexate versus control agent was associated with a higher risk of NMSC (HR, 1.97; 95% CI, 1.51 to 2.58) compared with a HR of 1.24 (95% CI, 0.97 to 1.58) in patients receiving anti-TNF monotherapy versus control subjects, emphasizing the possible potentiating effects of combination therapies for the development of cancers. This point is perhaps underlined by observations from a RCT of 180 patients with ANCA-associated (granulomatosis with polyangiitis) vasculitis. The occurrence of solid and skin malignancies in the group assigned to etanercept was increased above that expected from treatment with cyclophosphamide alone.[111]

Discordant results regarding cancer risk are likely explained by different patient populations and differing drug exposures. Meta-analyses of clinical trials generally reflect relatively short-term effects but offer the advantage of randomization, which should largely neutralize the variability introduced by individual comorbidities and previous drug exposures; long-term observational studies place more emphasis on mid- and long-term results. In either case, if cancer events occur in a nonlinear fashion with early dropout of individuals at risk for cancer, a conclusive analysis, even after several years of follow-up, may be unable to capture such a signal.

A crucial clinical question is whether patients with pre-existent cancers should be exposed to anti-TNF or other immunomodulatory therapies. Patients with pre-existent malignancies are generally excluded from clinical trials, and in clinical practice, clinicians may be reluctant to treat such patients with anti-TNF therapy, resulting in channeling of treatment with these agents toward low-risk cohorts. An analysis from the British Biologics Registry detected no increased risk of recurrent cancer in patients with pre-existing malignancy (IRR, 0.53; 95% CI, 0.22 to 1.26).[110] Also, data from the German Biologic Registry reveal no

**TABLE 37-2** Summary of Observational Studies of Malignancies Occurring In Patients with Rheumatoid Arthritis Treated with Anti–Tumor Necrosis Factor Agents

| Study, Reference Number | Registry | Intervention | Control nb-DMARDs | Control General Population | Adjusted Hazards Ratio (Intervention vs. Comparator/Control) | Adjusted Hazards Ratio (Intervention vs. General Population) | Risk of Bias |

Modified from Ramero, et al. Safety of synthetic and biological DMARDs: a systematic literature review informing the 2013 update of the EULAR recommendations for management of rheumatoid arthritis. *Ann Rheum Dis* 73:529–535, 2014.

significantly increased risk of recurrence in patients with a previous malignancy treated with anti-TNF agents (IRR, 1.4; 95% CI, 0.5 to 5.5).[100] However, very few events were included in these analyses, so definite conclusions about overall or cancer-specific risks in individual patients cannot be drawn.

## Rituximab

B cells appear to be involved in generation of antitumor responses and are important in maintaining inflammatory states, which promote carcinogenesis and tumor growth. The absence of B cells, for example, in hypogammaglobulinemia, has not been associated with increased susceptibility to cancers, and B cell depletion with rituximab has been shown to slow the growth of solid nonhematopoietic murine tumors.[112]

Pooled analysis of safety data from patients with RA treated with rituximab in RCTs with more than 5000 patient-years of exposure revealed an incidence of malignancy, excluding NMSC, of 0.84 per 1000 patient-years (SIR, 1.05; 95% CI, 0.76 to 1.42).[113] The incidence appeared

to be stable over multiple courses of rituximab, and no unusual pattern of malignancy type was observed.

### Abatacept

Abatacept is a fusion protein consisting of the extracellular domain of human cytotoxic T lymphocyte–associated antigen-4 (CTLA-4) linked to the Fc portion of human immunoglobulin. CTLA-4–mediated T cell suppression has been suggested to be important in the pathogenesis of several types of malignancies, especially malignant melanoma.[114] Because abatacept blocks the same signal that new anticancer treatments based on this interaction are intended to enhance, theoretically a potentially increased risk of malignancies may be seen with the use of this biologic. So far, however, no signal for increased malignancy risk, including lung cancers, has been noted in patients treated with this agent.[94,115]

### Tocilizumab

Tocilizumab is a humanized monoclonal antibody to the interleukin (IL)-6 receptor. IL-6 has an important role in inflammation and in the promotion of various types of malignancies, including suppression of apoptosis, promotion of angiogenesis, and induction of genes that mediate cell proliferation.[116]

Data from studies of rheumatoid arthritis, the disease in which experience with this agent is most extensive, so far have not revealed any signals of an increased incidence of cancer.[94] Labeling information for tocilizumab contains a general statement that "treatment with immunosuppressants may result in an increased risk of cancer," but no specific warnings are included.

### Anakinra

The IL-1 receptor antagonist, anakinra, has been best studied in RA. As is the case for most studies of biologic response modifiers, methotrexate usually has been administered concomitantly. The case rate for the development of malignant lymphoma with anakinra is 0.12 cases per 100 patient-years, with 8 cases of lymphoma observed among 5300 patients with rheumatoid arthritis treated with this drug in clinical trials for a mean of 15 months.[117] This represents a 3.6-fold higher than expected rate of lymphoma compared with the general population. The SIR for lymphoma in this study (3.71; 95% CI, 0.77 to 11.0) is consistent with odds ratios from other studies of patients with RA. A number of solid tumors have also been reported with this agent.[94]

### Tofacitinib

Similar to most other disease-modifying anti-rheumatic drugs, the Janus kinase 3 inhibitor tofacitinib carries a U.S. Food and Drug Administration black box warning regarding the potential risk for malignancy. Malignancies have occurred in RCTs of tofacitinib, but there are thus far no safety signals regarding malignancy risk, including data from a systematic review.[118]

## CANCER SCREENING IN PATIENTS WITH RHEUMATIC DISEASE

Evidence of cancer risk in patients with rheumatic diseases forms the basis for clinically useful recommendations regarding cancer screening. First, with respect to management of the inflammatory disease, it is imperative to achieve optimal disease control and the lowest level of clinical disease activity possible using the least intensive treatment regimen available. Second, patients for whom immunomodulatory therapy, including nb-DMARDs and biologic DMARDs, is considered should undergo routine cancer screening that is appropriate to their age, sex, familial cancer burden, and risk factors such as smoking. Third, because cancers may develop at an accelerated rate in the first few months to the first year or so of treatment, patients should be seen at frequent intervals and closely questioned and examined for signs and symptoms of malignancy, especially during this initial treatment period, and throughout the course of their disease.

Routine blood counts and differential blood cell counts should be performed at the initiation of treatment and as appropriate for the specific drug therapy used. Age- and gender-appropriate cancer screening for colorectal cancer, prostate cancer, breast cancer, and cervical cancer is advisable. In patients with particularly high cancer risk, such as dermatomyositis, assessment for tumor markers such as CA-125 and radiographic imaging of chest, abdomen, and pelvis may be appropriate yearly in the first year or two of the disease, and then as clinically indicated.[119]

Patients taking alkylating agents such as cyclophosphamide especially may be at particularly high risk of cancer. These patients certainly should undergo routine cancer screening Pap smears and urinalyses for at least 15 years from cyclophosphamide therapy. With these considerations, the morbidity and mortality experienced by patients with rheumatic disease can be favorably managed.

## CONCLUSION

Assessment of risk for malignancy in patients with rheumatic diseases is complex. Some rheumatic diseases such as dermatomyositis and Sjögren's syndrome appear to confer a particularly high risk of cancers, particularly lymphoproliferative disorders. Many of these diseases are relatively rare, so that large patient cohorts required for more precise assessment of risk are not available or must be studied over long periods of time to develop stable risk estimates.

Malignancy and perineoplastic syndrome should be considered when patients present with musculoskeletal symptoms caused by an underlying malignancy, or noted as symptoms and signs associated with the presence of an underlying malignancy in a patient with a pre-existent autoimmune disease.

Most of the agents used in the treatment of these diseases are purposefully employed to modulate the immune response, and some, including the alkylating agents, are known carcinogenics. Others may modulate immune response to decrease tumor surveillance. Further complicating the assessment are the individual susceptibility host factors, including the presence of oncogenic genes such as

*Blc-2*, and family history and environmental factors such as viruses, which may enhance the carcinogenic potential of the treatments.

Recommendations for treatment must include a general understanding of the disease and treatment-related malignancy and individualized discussion with the patient regarding risks and benefits of treatment as they relate to disease activity and severity and, most important, patient preference.

CHAPTER 38

# Introduction to Physical Medicine, Physical Therapy, and Rehabilitation

Maura D. Iversen

**KEY POINTS**

- The goals of rehabilitation are to maximize function and participation and to minimize activity limitations and impairments.
- The International Classification of Functioning, Disability, and Health provides the framework for rehabilitation.
- Modern rehabilitation is interprofessional and uses a patient-centered approach.
- Exercise is consistently effective in the treatment of various rheumatologic diseases.
- Physical modalities may be used as an adjunct to active therapies.
- Rehabilitation includes the training of individuals with impairments and disabilities, as well as adaptations of the environment to enhance participation.

Rehabilitation is a specialized medical field that combines medical therapy and nonpharmacologic interventions with the goals of maximizing function, independence, and participation, and ameliorating symptoms. The rehabilitation community has embraced the International Classification of Functioning, Disability, and Health (ICF)[1] as a framework to develop interventions to address the consequences of disease, communicate about strategies that enable individuals to engage fully in society, and formulate rehabilitation research[2-7] (Figure 38-1).

Rehabilitation interventions are multimodal and diverse and are designed to help individuals with arthritis live with their disease.[8-15] Exercise is the most studied and best proven intervention.[15-17] Physical modalities such as ultrasound, transcutaneous electric nerves simulation (TENS), and heat are adjuncts to exercise and show modest benefits with respect to pain relief, extensibility of tissue, and relaxation.[8-10,13-15] Orthotics, ambulatory devices, splints, and adaptive devices enable patients to navigate barriers and to fully participate in society.[18-20]

Musculoskeletal rehabilitation programs are based on the disease state and severity, the use and type of medications, and social, psychological, and environmental factors. This chapter provides an introduction to physical medicine and rehabilitation with an emphasis on nonpharmacologic interventions. Key principles of rehabilitation will be discussed, and management strategies for specific rheumatologic conditions will be highlighted.

## BRIEF HISTORY OF REHABILITATION IN RHEUMATOLOGY

Early rheumatology rehabilitation focused on bed rest, splinting, and range-of-motion (ROM) exercises. Physicians and rehabilitation specialists believed that physical activity and strenuous exercise would produce pain, increase joint swelling and temperature, and accelerate joint damage. In the 1940s, with the introduction of steroids, highly efficient and potent anti-inflammatory drugs, the rehabilitation focus shifted toward splinting and mobilizing patients with assistive devices to promote function. Surgical approaches such as joint replacements were used in the 1960s and 1970s to "stop" disease progression, and rehabilitation interventions were focused on post-operative protocols to enable patients to regain function and maximize independence. Throughout the 1970s and 1980s, with the proliferation of disease-remitting agents, such as Myochrysine, methotrexate, and sulfasalazine, rehabilitation regimens began to incorporate dynamic exercises and functional activities earlier in the disease process. Researchers also began to evaluate the impact of isometric and low-intensity isotonic exercise on immune response and function. Early data from these trials suggested positive effects on disease activity and strength.[21,22] While more medications entered the market and the prevalence of disease-modifying antirheumatic drugs (DMARDs) expanded in clinical practice, rehabilitation research shifted to the evaluation of various intensities, frequencies, and modes of exercises on patient outcomes. From the mid-1990s onward, studies of aerobic exercise illuminated the benefits of aerobic conditioning for cardiovascular function without deleterious effects on joints and soft tissue.[23-25] In the 21st century, with the use of advanced radiologic techniques and the advent of biologic therapies, researchers are investigating the impact of weight-bearing activities of various intensities on joint integrity[26] and are embracing a public health perspective through the promotion of physical activity designed to improve the quality of life, function, and participation.[27,28]

## GOALS OF REHABILITATION, REHABILITATION TEAM MEMBERS, AND MODELS OF TEAM CARE

Rehabilitation interventions address all aspects of the patient's condition with the aim of maximizing function, independence, and participation in society. As such, interventions range from the prescription of adaptive devices,

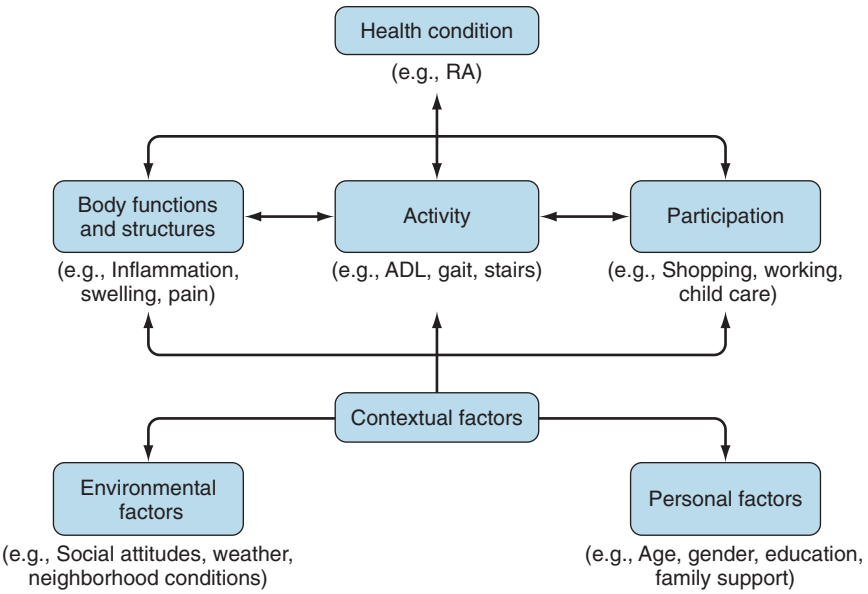

**Figure 38-1** Application of the International Classification of Functioning, Disability, and Health in rheumatoid arthritis (RA). ADL, Activities of daily living.

such as splints, orthotics, and ambulatory devices, to the use of physical modalities and instruction in exercise and self-management strategies (e.g., relaxation and proper rest). Rehabilitation specialists are educated to assess environmental factors so that they can best address barriers and facilitators that affect their patients.[29]

The initial phase of the rehabilitation process involves a comprehensive assessment of all dimensions of the patient's life and condition. Given the fluctuating course of many rheumatologic conditions, a coordinated effort by a variety of skilled rehabilitation specialists is required. The structure, function, and resources of the medical system in which the patient resides influence the team composition.[30,31] Physiatrists, or rehabilitation medicine physicians, are educated in medicine and rehabilitation to treat patients and refer to, and/or supervise, other skilled rehabilitation professionals.[29] These physicians typically are responsible for the care of patients with arthritis. However, in some circumstances, the rheumatologist may be the only physician involved in the patient's care. Other professionals involved in patient care are primary care physicians, nurse practitioners/nurse specialists, nurses, physical therapists, occupational therapists, social workers, nutritionists, psychologists, podiatrists, and vocational rehabilitators, who work with the patient's family.[30]

Comparative studies of team care delivery versus individual practitioner models indicate that coordinated team efforts yield better outcomes.[32-34] In all cases, the patient is the focal point of the team. Traditional models of team care are categorized as interdisciplinary/interprofessional, multidisciplinary, or transdisciplinary. In the interdisciplinary/interprofessional model, each professional conducts an independent patient evaluation and shares this information during team meetings to facilitate integrated team goals. Negotiation, communication, and collaboration are prevalent principles. Multidisciplinary team care does not foster intercommunication between professionals in a coordinated manner.[35] Rather, each professional conducts an examination and develops separate goals for care in concert with the patient, and documents findings. The transdisciplinary model allows for the transference of professional roles by crossing professional boundaries (e.g., a physical therapist can perform some functions of a nurse).[36] Any of these models of care may occur in inpatient or outpatient settings.

Although team care has been widely used in Europe,[37] this is not the case in North America, in part due to budgetary constraints and shortages of health care professionals, especially in rural areas. Consequently, innovative care models such as the clinical nurse-specialist model,[37,38] the primary therapist model,[36] and telemedicine have emerged.

## INTERNATIONAL CLASSIFICATION OF FUNCTIONING, DISABILITY, AND HEALTH: A FRAMEWORK FOR REHABILITATION MANAGEMENT

The ICF provides a framework for the development and implementation of rehabilitation interventions[1] by systematically organizing various aspects of an individual's health condition. The term *functioning* describes body functions, activities, and participation; the term *disability* refers to impairments, activity limitations, and participation restrictions. The ICF also considers environmental (e.g., stairs and curbs) and personal factors (e.g., attitudes and beliefs) that interact with body functions, body structures, activities, and participation.[1] This framework integrates aspects of the biopsychosocial medical model with an ecological perspective. The equal emphasis on ecological factors, such as personal and environmental contextual factors, helps rehabilitation specialists identify and address elements that may facilitate or present barriers to obtaining independence. The ICF definitions serve as a common language for providers to communicate about patients' health conditions, interventions, performance of activities and participation in society[1-8] (Figure 38-1). Researchers use the ICF to solidify and examine core constructs relevant to clinical studies of

rehabilitation.[3,6,7] These core sets have been compared with well-validated outcome measures to identify the most salient measures for rehabilitation clinical trials.[3]

## ASSESSMENT TOOLS AND THE REHABILITATION CYCLE

The first step in rehabilitation is problem identification based on a comprehensive history and physical examination using reliable and valid health measurements. These data are used to develop interventions and to evaluate outcomes. Rehabilitation health professionals use a variety of assessments, including the following:

- Technical measures: electrophysiologic, biomechanical, and computerized devices
- Clinical tests: ligament laxity tests, ROM, and strength testing
- Performance measures: gait velocity, mobility and balance tests
- Patient-centered measures: patient and proxy self-reports on health status, quality of life, and health preferences

Because the primary goal in rehabilitation is to diminish impairments, restore function, and facilitate engagement in social activities, the emphasis of a rehabilitation examination is on assessment of functioning and societal participation.[35]

Body structures and function elements, such as joint ROM, may be assessed subjectively through simple observation, goniometry, or high-speed cinematography. Goniometry, measurement of joint ROM by using a device called a *goniometer*, is often used in clinical settings because it is inexpensive, easy to perform, and psychometrically sound. Muscle strength is frequently assessed by manual muscle testing procedures, although its reliability and validity varies by joint location and by disease. Quantitative methods of maximal isometric strength measurement with hand-held dynamometers are reliable in patients with inflammatory arthritis[35,39,40] and in those with degenerative lumbar spinal stenosis.[41] Hand-grip strength can be measured reliably with a hydraulic hand dynamometer.[42]

Gait velocity, calculated as the time needed to walk a specific distance, is measured to assess walking mobility[43] and serves as a test of lower extremity function. The "Timed Up and Go" test[44] is a basic mobility test that measures the time it takes a patient to rise from an arm chair (seat height of 46 cm and arm height of 65 cm), walk 3 m, and return to and sit down in a chair. This performance measure has established normative values for different age groups.

Patient self-report measures are widely implemented in the core-set measures for various rheumatologic conditions. In inflammatory arthritis, the Health Assessment Questionnaire (HAQ) assesses dimensions of health, including disability, pain, medication effects, and costs of care.[45] A modified version of the HAQ (MHAQ) uses fewer items and maintains good psychometric properties, although differences in scores for disability are evident between the HAQ and the MHAQ.[46] The Katz Index of activities of daily living and the Macmaster Toronto Arthritis Preference Disability Questionnaire (MACTAR) also measure general activities of daily living. The MACTAR is unique in that it allows patients to choose which activities are important to them.[35]

A range of patient-oriented, disease-specific measures of function and symptoms may be used to assess pain, psychological status, well-being, fatigue, sleep, and quality of life.[12] Clinicians and researchers may have difficulty selecting the most appropriate measure for their purpose. To address this problem, one can refer to the ICF framework, which provides a clear picture of which health domains are addressed by each measure. There are also linking rules to relate technical and clinical measures, health status measures, and interventions to the ICF.[4]

## WHAT DO CURRENT GUIDELINES SUGGEST FOR REHABILITATION MANAGEMENT OF SELECT RHEUMATOLOGIC CONDITIONS?

Clinical guidelines for management consistently promote the use of exercise, physical activity, and physical therapy.[47-58] Recommendations are based on substantial evidence from randomized controlled trials (RCT) of exercise[59-63] indicating moderate effect sizes for the benefits of exercise for pain relief, function, and muscle strength. However, specific exercise prescriptions are not provided. Lack of specificity regarding exercise prescriptions originates from inconsistency in information regarding the intensity, frequency, mode, and duration of exercise in early clinical trials.[64] More recent studies adhere to standardized reporting criteria, such as the GRADE (Grading of Recommendations Assessment, Development, and Evaluation) framework,[65] thus providing detailed information about exercise interventions to enable better data synthesis. Information regarding accepted clinical rehabilitation is provided in the section addressing specific diagnoses and interventions.

## NONPHARMACOLOGIC INTERVENTIONS TO MANAGE RHEUMATOLOGIC CONDITIONS

Nonpharmacologic interventions used to manage rheumatologic symptoms include rest (total body or local), massage and trigger point techniques, exercise, assistive devices, orthotics and splints, counseling, education and self-management, manual therapy/mobilization, gait training and instruction in ambulatory devices, mobility devices, ergonomic modifications, and vocational rehabilitation. Table 38-1[8,13,66-76] provides a description of the interventions and their role in management. Among these, exercise, patient education programs, and self-management interventions are the best studied and the most effective. Across diseases, exercise interventions, whether dynamic or static, yield moderate improvements (effect sizes of 4 to 6) in strength, pain, and function, and produce small to moderate improvements in mood, quality of sleep, sleep patterns, and psychological well-being.[15-17,62-64,77] Exercise improves endurance and reduces inflammation.[78-80]

Patient education is an integral component of rehabilitation management. Patient education programs provide structured information about disease, medications and their use, when and how to perform exercise, disease management strategies (e.g., energy conservation and rest), and community resources. These programs are distinct from self-management interventions in that they are often provider driven and formulated, and focus on information dissemination versus behavioral interventions.[81] For example,

**TABLE 38-1** Definitions, Descriptions, and Purposes of Common Rehabilitation: Interventions to Manage Symptoms of Arthritis

| Intervention | Description |
|---|---|
| Energy conservation/ total body rest | Important with inflammatory rheumatic diseases to have intermittent rests during the day (half hour) and 8-10 hours of rest per night.[83] |
| Local rest/resting splints | Resting splints (worn at night or during periods of total body rest to prevent joint movement) provide local rest to joints and maintain joint alignment. In rheumatoid arthritis (RA) and other systemic inflammatory disorders, resting wrist splints are well tolerated and effective.[14] |
| Manual therapy/joint mobilization/ manipulation | Performed as low- or high-velocity, small- or large-amplitude passive movement techniques. Flexibility and strengthening exercises follow manual therapy/mobilization to gain full benefit. Evidence is strongest in treating hip and low back disorders, but effects are small.[64,103,105] |
| Trigger point therapy | Used for muscle pain. Consists of ischemic compression of trigger points, followed by isotonic contractions or muscle tissue stretching. Additional techniques include myofascial release, trigger point injections, trigger point dry needling, and intramuscular manual therapy. A local twitch response, provocation of referred pain, and subsequent relaxation of the taut band indicate successful application.[35] |
| Massage | Increases local blood and lymph flow, facilitates muscle relaxation, and reduces muscle stiffness, pain, and spasm. Techniques include gliding, kneading, deep friction, and percussion. Gliding and kneading reduce muscle tension, improve circulation, and decrease edema. Friction breaks up adhesions. Lymph drainage increases lymph flow and decreases edema. Massage is contraindicated for malignant tumors, open wounds, thrombophlebitis, and infected tissues. Lymph drainage should be avoided in patients with congestive heart failure.[35,67] |
| **Exercise** | |
| Range-of-motion (ROM) and flexibility exercises | Maintains joint movement and function and may be performed passively (by therapist) or may require active patient participation. In active-assisted exercises, the patient exerts some force with joint movement but is assisted by the therapist. Active ROM exercises require the patient to exert muscle effort to achieve the desired ROM.[35,83] Flexibility or stretching exercises enhance extensibility of muscle tissue. Stretching is best performed by using gentle, smooth movement, and then holding the stretch for 2 to 15 sec. |
| Isometric (static) exercise | Muscle contraction performed without a change in joint range or muscle length. These exercises produce less strain on joints than is produced by dynamic exercise.[83] |
| Isotonic/dynamic/ isokinetic exercise | Isotonic exercises require changes in muscle fiber length by elongating (eccentric) or shortening (concentric). These exercises involve movement through a fixed ROM at a fixed rate (velocity) against variable resistance. A machine provides resistance and rate of movement that matches exactly the force generated by the patient at any point in the range. This equipment can calculate the torque developed during the exercise activity.[35] *Note:* Avoid in the presence of inflammation, popliteal cysts, and joint derangement.[83] |
| Aerobic conditioning or endurance exercise | Provides cardiovascular pulmonary benefits, improves muscle strength, and reduces inflammation and weight. Modest effect sizes for these outcomes are achieved when exercises are performed at moderate levels of intensity for extended periods. Modes of aerobic exercise include walking, running, hiking, cycling, swimming, and stair climbing.[23-25] |
| Aquatic exercise, spa therapy, balneotherapy | Based on physical properties of water (i.e., buoyancy, molecule adhesion, temperature), provide physiologic benefits such as muscle relaxation and ease of movement. Exercises performed in water allow buoyancy to support body weight and unload joints. Water adhesion properties may provide resistance when exercising. Diuresis and hemodilution are physiologic effects experienced with aquatic exercise. The recommended water temperature is 33°C to 34°C (92°F to 94°F). A systematic review of randomized controlled trials investigating balneotherapy has reported positive findings. However, the evidence was insufficient to allow formal conclusions about the efficacy of balneotherapy for patients with arthritis.[10] |
| **Physical Modalities** | |
| Superficial heat/cold therapy | Radiation (infrared light) and conduction (hot packs, paraffin, or water) are mechanisms for superficial heat/cold generation that are applied for 20 minutes. Superficial heat increases the pain threshold, decreases muscle spasms, and produces analgesia by acting on free nerve endings. *Note:* Avoid heat therapy in the presence of acute inflammation or in people with altered sensation. Cold therapy may be applied using ice packs, ice massage, vapocoolant sprays, or cold water baths. Cold therapy induces superficial and intra-articular tissue vasoconstriction, reduces local metabolism, and slows nerve conduction, thereby reducing pain and inflammation. Complications of cryotherapy include frostbite, cold-induced urticaria, and nerve damage. Use cryotherapy with caution in patients with Raynaud's phenomenon or with cryoglobulinemia.[35] Although evidence for physiologic benefits of heat and cold therapy indicates small effects,[9] patients report psychological benefits. |
| Electrotherapy | Uses electricity to stimulate nerves and muscles and to alleviate pain. Surface electrodes are the common transfer medium. Only electroacupuncture and dorsal horn stimulation use needle electrodes percutaneously. Electrotherapy uses direct continuous galvanic currents and modulated direct currents. Galvanic currents decrease pain conduction in slow unmyelinated nerve fibers (C fibers) to reduce pain. Modulated middle-frequency electrotherapy results in inhibition of pain-related potentials at spinal and supraspinal levels. Electrical stimulation of fast-conducting myelinated nerve fibers can partially decrease pain through inhibition of pain impulses carried more slowly by unmyelinated fibers. Faster impulses arrive at the level of the dorsal horn first and "close the gate." Transcutaneous electrical nerve stimulation (TENS) is used for musculoskeletal pain, post-traumatic or post-surgical pain, peripheral nerve injury, neuropathic pain, and sympathetically mediated pain.[12,35] Electrotherapy is contraindicated in patients with cardiac pacemakers or implanted cardiac defibrillators, and is used with caution in patients with atrophic skin.[35] A systematic review of randomized controlled trials of TENS in arthritis reports inconsistent results in managing RA symptoms[12] and low back pain, and some benefits for pain and knee stiffness in patients with knee osteoarthritis (OA). |

**TABLE 38-1** Definitions, Descriptions, and Purposes of Common Rehabilitation: Interventions to Manage Symptoms of Arthritis—cont'd

| Intervention | Description |
|---|---|
| Deep tissue heating/ ultrasound/ diathermy | Parameters for application vary by the device; the device must be applied by a skilled provider owing to the risk of deep tissue burns of the skin, fat, muscles, and bones. Heating occurs mostly at tissue interfaces (e.g., bone–soft tissue interfaces). Ultrasound may penetrate 7 to 8 cm of fat, but less than 1 mm of bone, depending on the energy level and frequency chosen. In practice, ultrasound with frequencies of 0.1 to 1 MHz can increase temperature by 4°C to 5°C at depths of 7 to 8 cm.[35] Two systematic reviews of ultrasound[8,71] reported small benefits for pain, knee and hand stiffness, grip strength, and tender and swollen hand joints.[8] *Note:* Avoid deep heating in patients with altered sensation, implants, or history of cancer. Ultrasound must be applied using continuous movement over joints and bony surfaces or in a water bath to avoid heating of bone. |
| **Devices to Stabilize and Protect Joints** | |
| Orthotics/braces | Orthotic devices include braces, splints, corsets, collars, and shoe modifications. Orthotic devices restore or maximize function by altering biomechanics through stabilizing, realigning, and/or maximizing joint position, thereby reducing pain. Orthotics provide some pain relief but inconclusive evidence of improved function long term.[18,19] Successful prescription and use of orthotics require the identification of functional limitations (on all International Classification of Functioning, Disability, and Health levels) and patient collaboration to adjust the orthotic. Devices can be simple and inexpensive, but may be specially designed and consequently expensive.[35] Bracing is prescribed to stabilize joints. The most common are knee braces typically prescribed for OA.[19] |
| Dynamic splints | Dynamic splints maintain joint alignment and reduce pain during functional activities. The most common dynamic splints used in RA are functional wrist splints, although many others are available for the small hand joints. In OA, thumb splints are common. A Cochrane review from 2003 concluded that dynamic wrist splints significantly increase grip strength but do not impact pain, morning stiffness, pinch grip, or quality of life. No evidence suggests that resting splints changed pain, grip strength, or the number of painful or swollen joints. Patients preferred using these splints to nonuse.[20,35] |
| Collars/corsets | Cervical collars include soft collars, Philadelphia collar, and sterno-occipitomandibular plaster immobilization. These provide varying levels of stability. None prevent subluxation or displacement.[69] Patients with night pain resulting from a cervical disk syndrome may profit from wearing a soft collar at night. Corsets and abdominal binders provide feedback but limited stability to patients in terms of body position.[35] |
| Assistive devices | A multitude of devices may be used to assist function and reduce barriers to independence. Examples include button hooks, long-handled reachers, sock aids, modified eating utensils (padded handles), bottle openers, and modified container lids. A physical or occupational therapist may recommend modified door handles, a raised toilet seat, a commode, safety bars on the bathroom wall, or a lift in the bath to ensure safety and maximize independence with hygiene activities. |
| Mobility devices | Mobility devices, such as canes, crutches (axillary, forearm, and platform), wheeled walkers, and wheelchairs, are used when walking is limited by lower extremity joint instability, pain, weakness, and fatigue or balance problems. These devices are easily accessible and provide immediate assistance, but they require more physical effort than is required for normal ambulation. The choice of a mobility device is based on impairments and resulting disability (e.g., patients with RA with bilateral upper extremity involvement and leg weakness may be safer ambulating with platform than axillary crutches). Patients with balance disturbances and leg weakness may be better suited for walkers. The device type also impacts the weight-bearing status. For example, a single-point cane can bear about 25% of body weight, axillary or forearm crutches approximately 50%, and a wheeled walker more than 50%.[70] Wheelchairs are necessary if patients are unable to walk with devices. In these cases, a wheelchair can improve the quality of life by maintaining some mobility. Individuals unable to navigate a manual wheelchair can profit from an electrical chair. Accidents can occur while traversing ramps, sidewalks, and streets.[35] |
| Vocational rehabilitation | Vocational rehabilitation is an interdisciplinary approach that enables patients to acquire and maintain gainful employment and varies among countries. A common feature consists of problem assessment at work and the development of individual solutions. Studies demonstrate that vocational support prevents or delays work disability and improves fatigue and mental health.[71] |
| Work hardening/ functional restoration programs | These highly structured, goal-oriented, individually tailored programs are provided by an interdisciplinary professional team to address functional, physical, behavioral, and vocational needs to facilitate return to work.[71] Work hardening programs bridge the gap between initial injury and return to work. Most programs include a formal worksite ergonomic to address workplace design issues and to reduce injury risk while improving function, as well as social interventions. The Commission on Accreditation of Rehabilitation Facilities defined and developed standards for work hardening practice to standardize program content and implementation.[71] Work hardening programs integrate real or simulated work activities to model appropriate behaviors and assess functional, biomechanical, neuromuscular, cardiovascular/metabolic, behavioral, attitudinal, and vocational performance.[71] A systematic review of these programs provides evidence for significant reductions in sick days. |
| Self-management and patient education | Patient education is defined as a set of planned educational activities used to improve a patient's health behaviors and/or health status. Most patient education programs are provider driven and developed. Self-management programs are patient oriented and patient active, and combine education with cognitive-behavioral strategies to influence patients' attitudes toward disease and disease management.[81,82] |
| Cognitive-behavioral therapy (CBT) | CBT acknowledges that pain and its resulting disability are influenced by somatic pathology, and by psychological and social factors. In general, three behavioral treatment approaches are distinguished: operant, cognitive, and respondent. The primary focus is to reduce disability. A review of 21 studies found no significant differences between the various types of CBT; also, CBT did not differ from exercise in its benefits. A conclusion regarding whether clinicians should refer patients with chronic low back pain to behavioral treatment programs or to active conservative treatment was not possible. |

ankylosing spondylitis education programs teach patients about their disease, medications, importance of good posture, daily activities that promote spinal extension, and coping skills.

Self-management programs are patient focused, patient driven, and action oriented.[81] They combine education, behavioral interventions, and cognitive strategies to enable patients to problem-solve, cope, and develop strategies to maximize function and independence. These programs assess and influence patients' attitudes and beliefs about disease and their ability to manage their disease. Self-management programs demonstrate benefits with respect to disease outcomes[81,82] and have proved cost-effective.[82]

Evidence of the benefits of physical modalities, therapeutic relaxation techniques (massage, trigger point therapy), splints, orthotics, and gait interventions varies across intervention type and disease. Overall, the evidence is weak.[8-10,12,83] However, it is important to note that relaxation techniques, alternative therapies (acupuncture), and physical modalities are adjunct therapies designed to prepare patients for dynamic exercise, flexibility training, or gait training and are not stand-alone interventions.[12,83,84] Additionally, many patients report satisfaction with and preference for these therapies.[84]

## PRINCIPLES GUIDING REHABILITATION IN PEOPLE WITH RHEUMATOLOGIC CONDITIONS

Research and clinical management outcomes suggest the following guiding principles:

- Primary, secondary, and tertiary programs are integral to patient care. Primary prevention focuses on preventing disease. Secondary prevention refers to detection of disease before symptoms arise. Tertiary prevention, the most common in arthritis, focuses on interventions for people already experiencing symptoms to ameliorate these and to maximize function, independence, and participation.
- Exercise prescriptions for people with systemic inflammatory diseases are developed based on the disease state (active vs. inactive), disease severity, patient preferences and goals, medications used and their corresponding side effects, and latency periods.[83]
- Persons with arthritis are less physically active than their healthy counterparts.[85-87]
- Asymptomatic heart disease may be disproportionately present in people with systemic inflammatory disease, and their response to exercise may be altered; therefore careful monitoring of cardiovascular pulmonary response is needed before, during, and after exercise testing and participation.[83]
- Dynamic resistance strengthening exercises should be avoided in the presence of joint derangement and popliteal cysts.[83]
- During periods of active myositis and elevated creatine phosphokinase (CPK) levels, activities should be limited to ROM exercise and functional activities of daily living, and rest should be encouraged.

The Centers for Disease Control and Prevention (CDC) in conjunction with the American College of Sports Medicine (ACSM) has established physical activity guidelines to promote the health of all Americans, including people with rheumatologic diseases (Table 38-2).[88,89,90] The CDC deliberately framed these recommendations simply reporting a range of minutes of exercise versus traditional physiologic parameters to enable consumers to interpret activity to meet these recommendations. Presently, physical inactivity among people with doctor-diagnosed arthritis in the United States is a major public health issue; only 17.2% of people with arthritis meet the CDC recommendations for moderate physical activity.[88]

**TABLE 38-2** Centers for Disease Control and Prevention and American College of Sports Medicine Guidelines for Physical Activity

| |
|---|
| 30 minutes of moderate* physical activity, 5 days per week |
| *or* |
| 20 minutes of vigorous activity, three times per week |

**Moderate activity* is defined as an increase in breathing or heart rate; perceived exertion in the range of 11 to 14 out of 20 on a perceived exertion scale[90] or 3 to 6 metabolic equivalents of task, or any activity that burns 3.5 to 7 kcal/min.[88,89]

## REHABILITATION OF SELECT RHEUMATOLOGIC CONDITIONS

In this section, select conditions are discussed, along with the evidence for rehabilitation interventions. Diseases that have similar attributes are grouped together, although they are distinct entities. In this manner, the rationale for interventions based on similar impairments, functional limitations, and activity participation can be delineated.

### Rheumatoid Arthritis and Inflammatory Arthritis

Both rheumatoid arthritis (RA) and psoriatic arthritis (PsA) are chronic systemic inflammatory rheumatologic disorders affecting connective tissues and joints. Of the two conditions, RA is more prevalent. Although the origin and prevalence of RA and PsA differ, the two disorders have similar symptoms. For example, patients are seen with polyarticular symmetric joint involvement, malaise, morning stiffness, pain relievable with activity, muscle weakness, enthesitis and/or plantar fasciitis, and cardiovascular pulmonary involvement. Both diseases are characterized by exacerbations and remissions. Differences between these diseases are noted with respect to the joints involved, integumentary involvement, dactylitis,[91] and predominant pathology. The primary pathology in PsA is enthesitis, and the axial skeleton is chiefly involved. Chronic inflammation eventually may lead to spinal ankylosis, significantly impacting trunk ROM and rib cage excursion. RA is a disease of the synovium that typically involves the hands, feet, wrists, and weight-bearing joints. Although RA does not affect most of the spine, subluxation of the atlantodental joint can occur.[83]

Systemic features lead to impairments such as fatigue, malaise, fever, sarcopenia, reduced aerobic capacity, restricted joint range of motion, postural instability, cardiovascular pulmonary dysfunction, and depression.[91,92] Both conditions are associated with significant disability and early death. Medical management includes the use of

**TABLE 38-3** Physical Therapy Interventions for Various Stages of Disease Activity Inflammatory Arthritis

| Acute Inflammation | Subacute Inflammation | Inactive/Chronic |
|---|---|---|
| Rest and continue physical activity as tolerated | Moderate physical activity (4-5x/week for 30 minutes) | Vigorous physical activity (3x/week for 20 minutes) or moderate physical activity (5x/week for 30 minutes) |
| Passive and active range-of-motion (ROM) | Active ROM | Active ROM |
| Isometric exercises | Dynamic exercises with resistance, aerobic exercise<br>70%-80% heart rate | Dynamic exercises with resistance, aerobic exercise<br>70%-80% heart rate |
| Modalities for pain and inflammation | Ergonomic interventions, work accommodations | Ergonomic interventions, work accommodations |
| Resting splints, dynamic splints, orthoses, and assistive/ambulatory devices as needed | Resting splints, dynamic splints, orthoses, and assistive/ambulatory devices as needed | Dynamic splints, orthoses, and assistive/ambulatory devices as needed |

biologics, DMARDs, steroids, nonsteroidal anti-inflammatory agents and biologics. Rehabilitation professionals must be aware of medication indications, potential side effects, and the latency period to effectiveness if they are to develop treatments that adjust as responsiveness to medications increases.

Given the fluctuating nature of both diseases, the rehabilitation interventions selected vary by disease activity. Table 38-3 provides an intervention algorithm that illustrates the different modes of exercise and interventions used to manage these conditions during acute, subacute, and chronic disease stages. When RA or PsA is highly active, patients may report low-grade fever, fatigue, or malaise, and may be seen with warm, swollen, and tender joints. Adaptive shortening of soft tissues, joints, and tendons may occur secondary to inflammation and as the result of protective joint splinting in response to pain. In RA, metacarpophalangeal and interphalangeal joint subluxation, as well as ulnar deviation of the fingers and radial deviation of the wrists, is prevalent, whereas dactylitis may be present in PsA.[91] Soft tissue inflammation may lead to atrophy of the foot intrinsic muscles and loss or subluxation of plantar fat pads in both, resulting in plantar fasciitis and enthesitis. Eventually, loss of cartilage may result, with severe disease, joint subluxation, and derangement. These joint changes may lead to functional limitations, gait abnormalities, and deconditioning.[83,91]

Interventions used to manage acute inflammatory symptoms include patient self-management strategies, ROM exercises, isometric (static) exercises, physical modalities, total body rest, and splints. Exercise frequency and intensity is generally set at three to five repetitions, twice a day. The greatest evidence for benefits from interventions is for exercise regardless of mode of exercise. To enhance adherence, patients are instructed to conduct daily joint checks, a simple check of each joint to determine which are most limited and can serve as the focus of exercises for that day. Energy conservation strategies are important. Patients are advised to sleep 8 to 10 hours per night and to rest frequently during the day. Resting and dynamic splints can help maintain joint alignment, reduce pain, and control inflammation. Resting splints are used when the patient is sleeping to hold joints in a neutral position, restricting all movement. Dynamic splints allow joint movement to accommodate functional activities. During the acute inflammatory stage, cold therapy (cold packs, ice massage) is preferred versus heat to reduce swelling and alleviate pain. However, thermal modalities (heat/cold) are contraindicated in people with altered sensation and vascular conditions.[83] Assistive/adaptive and ambulatory devices (e.g., long-handled reachers, crutches) may be used to maximize function and participation. Ambulatory devices and orthotics are particularly important in the presence of foot involvement and deformities to redistribute weight and alter lower extremity biomechanics. Orthotics may also improve function and reduce pain.[18] When wrists and hands are involved, platform attachments to ambulatory devices are warranted. In all cases, patient preferences need to be considered when ambulatory devices are selected.

When symptoms subside (e.g., subacute stage), interventions may be modified to include increased repetitions of ROM exercises, with progression from isometric to dynamic exercises (five to ten repetitions of each exercise, three times per day). However, if popliteal cysts are present, active resistive exercise should be avoided. Flexibility exercises are initiated to reduce soft tissue tightness and contractures. The use of heat therapy and/or massage before stretching may reduce muscle spasm and enhance tissue flexibility. Clinical trials of thermotherapy report small effects for relief of muscle spasm, pain, and extensibility of soft tissue.[9] TENS, laser, massage, and trigger point therapy provide inconsistent but small benefits.[8,9,13,93-95] Core stability and balance exercises may be used to address muscle imbalances. RCTs of exercise at low to high intensity demonstrate moderate effects in improving strength, function, and mood state, and in reducing pain, stiffness, and inflammation, without deleterious effects on joints.[12,14,,21,94,95] Aquatic exercises are encouraged to promote flexibility, improve gait patterns, maximize strength, and increase independence. The buoyancy of the water facilitates movement and reduces joint loading.

With stable disease, patients should incorporate dynamic strengthening exercises with resistance (eight to ten repetitions a day). Studies suggest that dynamic exercises can effectively increase muscle strength, physical capacity, and aerobic capacity.[21] It is imperative to initiate aerobic exercises (30 minutes, three to five times per week) to address cardiovascular risk, improve aerobic performance, and increase muscle strength.[96,97] Patient counseling regarding physical activity and active lifestyles should be emphasized

to prevent secondary effects of inactivity.[85-87] The most common modes of physical activity and exercise include low-impact exercise, such as walking programs, aquatics, dance, and cycling, and dynamic exercises with resistance. Recent clinical trials of high-impact physical activities report significant improvements in aerobic capacity, grip strength, physical activity, anxiety, and depression.[26] High-intensity exercises appear to be safe and effective, except in the presence of joint changes in large weight-bearing joints, joint derangement, and cartilage loss before initiation of weight-bearing activities.

## Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a systemic inflammatory disease that predominantly affects women in their childbearing years and is more common among African-Americans. Its cause is unknown. SLE affects multiple organ systems, including the joints, skin, kidneys, heart, lungs, brain, and gastrointestinal tract. Fatigue is prevalent and may arise from myositis, anemia, depression, pulmonary disease, or deconditioning. Joint involvement is not uncommon. If present, the small joints of the hands, especially the proximal interphalangeal joints, may be involved, and recommendations similar to those for RA apply. Aseptic necrosis of the hip may occur. With unilateral hip disease, use of an ambulatory device on the contralateral side reduces acetabular loading and hip abductor muscle activity, thereby decreasing joint hip load and pain. Eventually, the patient may require a total joint arthroplasty.[83]

Asymptomatic coronary heart disease is a major cause of mortality. Thus a comprehensive cardiovascular pulmonary system review is needed along with exercises modes to enhance cardiovascular performance, such as biking, walking, and dynamic exercises at moderate intensity (50% to 70% one repetition maximum). For safety, vital signs are assessed at baseline and at regular intervals during the exercise session.[98] Patients who are severely deconditioned may benefit from interval training (short bouts of 10 to 15 minutes of exercise twice a day) to enhance aerobic conditioning.

Studies of exercise in SLE are limited. In an earlier trial of endurance training that used stationary cycles with individually tailored resistance settings based on submaximal exercise testing, patients with SLE demonstrated small to modest effects on function but no significant impact on $VO_2$max (maximal oxygen consumption).[99] A review of exercise for patients with SLE concluded that patients with mild to moderate SLE benefit from exercise of moderate to high intensity, yielding significant benefits for aerobic capacity, fatigue, physical function, and depression.[100]

## Osteoarthritis

Osteoarthritis (OA) is a progressive, multifaceted disease of the cartilage that can lead to cartilage and bone loss. Typical joints involved include hips, knees, spine, and hands (distal and proximal interphalangeal joints, first carpometacarpal, and first metatarsal phalangeal). Intrinsic and extrinsic factors, such as joint injury, malalignment, trauma, obesity, and quadriceps weakness, are associated with the development of OA. Patients typically note short-term morning stiffness (<30 minutes) or stiffness after prolonged inactivity. The combination of excess weight and poor joint biomechanics increases OA risk approximately threefold.

Patients typically report specific joint pain, muscle weakness, and restrictions in ROM. Osteophytes and bone fragments may produce radicular pain if a nerve root is compressed and can limit ROM. Heberden's nodes at the medial and dorsolateral aspects of the distal interphalangeal joints and/or Bouchard's nodes at the proximal interphalangeal joints may be present. Hip pain is frequently located at the joint line but may radiate to the groin, buttocks, anterior thigh, or knee. Reduced hip ROM impacts function and hygiene. Knee osteoarthritis (KOA) may appear as knee instability, restrictions in ROM, crepitus, pain with loading activities, or buckling of the leg with transfers and ambulation.

Common interventions to manage OA include dynamic strengthening exercises (both open and closed chain exercises), core stability exercises, education, balance activities, aerobic exercises (biking, swimming), joint mobilization and manipulation, bracing (severe cases), gait training, use of orthotics, and appropriate footwear.[58] Thermotherapy, including deep heat applications (ultrasound), may alleviate pain, enhance tissue extensibility, and reduce stiffness.[14] Paraffin is useful for hand treatment because it provides a medium for dispersing heat over small joints. Exercise can effectively improve function, reduce stiffness, and maximize independence. Recent reviews and synthesis of exercise literature for KOA and hip OA, provided at varying intensities, frequencies, and durations, report significant moderate gains in muscle strength and function (effect sizes from 0.3 to 0.6).[16, 62-65,75,101-103] The emphasis of patient education is on joint protection techniques, activity modification, weight reduction, and strategies to unload the joint.

Manual therapy techniques for patients with KOA include tibiofemoral and patellofemoral joint mobilization. Manual therapy is followed by stretching of the quadriceps, hamstrings, tensor fascia, iliotibial band (ITB), hip flexors, and gastrocnemius soleus, and with soft tissue mobilization techniques. These combined interventions yield the greatest benefits for joint range and function.[75,81,101-103] Open-chain isometric exercises, such as quadriceps exercises, are used with progression to closed-chain weight-bearing exercises, such as mini-squats and step-ups.[64] Balance activities, such as single-leg stance and hop, are designed to facilitate co-contraction, and coordination of muscle firing useful for promoting knee stability. Sensorimotor interventions may provide necessary proprioceptive input, but their efficacy is still unknown.[104] Lateral wedge orthoses in patients with medial compartment KOA assist with altering biomechanical knee loading and are well tolerated.[19] With progressive disease and instability, knee braces are used to decrease medial compartment pressures resulting from varus positioning. Systematic reviews of knee bracing report limited benefits for pain relief and function. However, it is important to note that adherence to these devices is problematic.[19]

Hip OA often results in restrictions in internal hip rotation and impacts gait. Manual techniques for the hip, such as joint mobilizations and manipulations, aim to improve the elasticity of the joint capsule and surrounding muscles. The combination of mobilization and exercise appears to be

more effective than exercise alone.[16,64,105] Ambulatory aids (canes, crutches) help unload the joint and allow patients to maximize independence.

## Ankylosing Spondylitis

Ankylosing spondylitis (AS) is a systemic inflammatory disease that targets the sacroiliac and axial joints. Systemic features include fatigue, malaise, and sarcopenia, resulting in reduced physical activity engagement. Enthesopathy is common and impacts gait and transfers. With persistent inflammation, ankyloses of the spine can occur,[106] limiting trunk ROM and rib cage excursion. AS may also involve the hip and shoulder joints. Cardiovascular pulmonary manifestations may be seen; when they are coupled with trunk and rib cage restrictions, as well as the potential for costochondritis, aerobic capacity may be dramatically impacted.[83]

Rehabilitation interventions for patients with AS include physical modalities, such as thermal therapy to relax soft tissues and prepare the patient for flexibility exercises, manual therapy, assistive and ambulatory devices, orthoses, and functional activities. The principles of physical modalities for people with AS are similar to those for those with PsA. Flexibility exercises are used to promote extension and maintain a neutral spine. Incorporating posture and flexibility exercises into daily routines can enhance adherence and maintain joint ROM. For example, patients can be encouraged to read the newspaper while lying prone or to take stretch breaks during the day to avoid long periods of time sitting. Given the potential for reduced rib cage excursion, deep breathing exercises are used, although their efficacy is unproven. Evidence for dynamic progressive strengthening exercises of the postural muscles (at moderate intensity) and motor control activities demonstrate these exercises are useful for maximizing strength and function. A Cochrane review of three RCTs reported greater improvements in spinal mobility and patient global assessment among patients participating in supervised group exercise.[107] Aquatic exercises provide a nice alternative, and the buoyancy of the water can facilitate movement. However, studies of aquatic therapy for individuals with AS are limited and, at best, show small effects.[108] Ambulatory and assistive devices may be warranted as the disease progresses or to unload a painful hip. Patient education typically focuses on smoking counseling, joint protection, energy conservation, exercise, and coping strategies.

## Strategies to Increase Adherence to Exercise and Rehabilitation

Rehabilitation interventions require active patient participation and a commitment for benefits to be acquired. The team must always maintain a patient-centered focus and engage the patient in mutual goal setting and problem solving. Clear, concise communication about treatment expectations and the establishment of small, progressive, and achievable milestones are important. Potential barriers to exercise, such as fear of joint damage or exacerbation of pain, lack of social support for exercise, fatigue, lack of transportation, or cost, must be considered in the development of appropriate and acceptable interventions. With systemic inflammatory diseases, disease activity primarily influences the mode, frequency, and intensity of exercises prescribed, although other factors that influence intervention selection include disease severity, systemic manifestations, other comorbidities, and patient preferences. Self-management programs promote adherence to exercise and active lifestyles and are highly effective.[81] Referring patients to community resources such as Arthritis Foundation exercise programs (e.g., *Walk with Ease* and *Fit and Strong!*) allows them to develop social networks, to share their experiences in living with arthritis, and provides venues for exercise. Mobile applications to promote physical activity available free or with a modest cost, are currently undergoing testing as mechanisms to support an active lifestyle and promote social networking. Their effectiveness is unknown.

# CONCLUSION

Rehabilitation interventions comprise a vast array of interventions. Physical modalities are adjuncts to exercise and self-management and provide small benefits with respect to pain relief. Evidence for orthotics and bracing is weak, although adherence is a factor that influences results. Exercise is the most intensively studied intervention; it provides modest benefits for pain relief, strength, function, mood state, and joint stiffness across most disease entities. Selection of rehabilitation interventions for systemic inflammatory diseases is influenced primarily by disease state but is also dependent on disease severity, medication latency periods, comorbidities, disease severity, and patient preferences.

CHAPTER 39

# Pregnancy and Rheumatic Diseases

Lisa R. Sammaritano • Bonnie L. Bermas

**KEY POINTS**

- With careful planning and a team approach, most women with rheumatic diseases can have successful pregnancies.
- For best maternal and fetal outcome, patients with rheumatic diseases should conceive in periods of low disease activity and while on medications considered low risk for pregnancy.
- Rheumatology patients should undergo pre-pregnancy assessment to assess disease severity and activity, medication safety, and relevant autoantibodies.
- Not all anti-rheumatic medications can be used during pregnancy or breastfeeding, but recent data provide guidance for many commonly used medications.
- Use of effective and safe contraception is critical for rheumatic disease patients, especially those with severe disease, active disease, or those on teratogenic medications.

The predominance of many rheumatic diseases in women during their reproductive years makes management of pregnancy an important component of the comprehensive care of these patients. Advancements in disease therapies and identification of risk factors for poor pregnancy outcome allow many more patients to pursue pregnancy.

## INTERPLAY OF RHEUMATIC DISEASE AND PREGNANCY PHYSIOLOGY

**KEY POINTS**

- Normal pregnancy induces multiple physiologic changes that often impact manifestations of rheumatic diseases.
- Hypertensive diseases of pregnancy may complicate pre-existing rheumatic disease and be difficult to differentiate from active rheumatic disease.

Understanding potential interactions between pregnancy and rheumatic disease requires a basic knowledge of pregnancy physiology. Pregnancy affects the maternal immune system in multiple ways to ensure fetal survival. In brief, cell-mediated immunity decreases, immunoglobulin secretion increases, and pregnancy-specific proteins act to suppress lymphocyte function. Complement levels rise as a result of increased synthesis. The dominant T helper 2 cell cytokine profile, possibly important in sustaining pregnancy, may have varying implications for different autoimmune diseases.[1]

During pregnancy, a majority of the organ systems experience some degree of change. Intravascular volume increases by 30% to 50% and may be poorly tolerated by patients with significant renal or cardiac compromise. The glomerular filtration rate (GFR) increases by 50% in a normal pregnancy; as a result, patients with pre-existing proteinuria experience increased urinary protein excretion, which may raise concerns about active renal disease. Pregnancy induces a prothrombotic state, and the combination of estrogen-induced hypercoagulability, venous stasis, and compression by the gravid uterus elevates the risk of venous thromboembolism in a normal pregnancy by a factor of five. Red blood cell mass increases to a lesser extent than plasma volume, resulting in anemia that is secondary to hemodilution. Thrombocytopenia occurs in 8% of uncomplicated pregnancies. The white blood cell (WBC) count is elevated and the erythrocyte sedimentation rate (ESR) also rises, making both tests less useful as indictors of inflammation. Elevated progesterone levels in pregnancy decrease gastrointestinal motility and sphincter tone: in conjunction with uterine compression, these changes result in gastric reflux in as many as 80% of pregnant women. Slowed intestinal transit time contributes to an exacerbation of reflux and constipation in illnesses such as systemic sclerosis. Pregnancy-related rashes may occasionally be confused with autoimmune disease skin manifestations. A more common problem is facial and palmar erythema caused by pregnancy-induced vasodilatation mimicking inflammatory rash. Chloasma gravidarum, an estrogen-induced facial hyperpigmentation, may similarly suggest a malar rash. Hormone-induced ligamentous laxity often causes arthralgias that may be attributed to joint inflammation. Finally, reversible bone loss occurs with both pregnancy and lactation; this is especially worrisome for patients with pre-existing osteoporosis caused by rheumatoid arthritis (RA) or long-term corticosteroid use.[2]

Hypertensive disorders complicate as many as 10% of pregnancies in the general obstetric population and are more common in patients with rheumatic disorders. They are a major cause of maternal, fetal, and neonatal complications. Gestational hypertension and pre-eclampsia are both more common among women with systemic lupus erythematosus (SLE) and among women with renal disease of any etiology. The hypertension, proteinuria, renal insufficiency, and edema associated with pre-eclampsia can mimic lupus nephritis, scleroderma renal crisis, or vasculitis flare. Eclampsia, which includes seizures and rarely stroke, may be confused with central nervous system lupus or vasculitis.

HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome, a variant of severe pre-eclampsia, is characterized by the presence of hemolysis, elevated liver enzymes, and low platelets.

## GENERAL PRINCIPLES OF PREGNANCY AND RHEUMATIC DISEASE: PRE-PREGNANCY ASSESSMENT

**KEY POINTS**

**Rheumatic disease women should conceive during a period of inactive disease for optimal pregnancy outcome.**

**Preconception evaluation should include assessment for disease damage, current disease activity, safety of medications for pregnancy, and aPL, anti-Ro/SS-A, and anti-La/SS-B antibodies.**

General principles of pregnancy management for rheumatic disease patients include a structured pre-pregnancy assessment for risk for maternal and obstetric complications, communication of risk and prognosis through counseling, and coordinated rheumatology and obstetric care. Assessment of rheumatic disease patients considering pregnancy should follow the same protocol regardless of the specific diagnosis. Determination of risk should include identification of serious disease-related organ damage that might affect the patient's ability to safely carry a pregnancy, evaluation of current and recent disease activity, review of medication safety, and serologic evaluation for autoantibodies associated with adverse maternal, fetal, or neonatal outcome.

### Severe Disease Damage

Severe manifestations of disease damage may preclude pregnancy. These include severe cardiomyopathy, cardiac valve disease, pulmonary arterial hypertension (PAH), interstitial lung disease, neurologic manifestations, and renal insufficiency. PAH in particular is associated with a high risk of pregnancy-related mortality.[3] The most important predictors of permanent renal disease in pregnant women with chronic kidney disease (CKD) are GFR <40 mL/min/1.73 $m^2$ and proteinuria greater than 1 g/24 hours.[4] The potential complications associated with severe chronic disease manifestations make pregnancy extremely high risk for these patients. If such patients are intent on having a biologic child, it may be appropriate to consider the safety of in vitro fertilization (IVF) with a surrogate.

### Disease Activity

Pregnancy reports in almost every rheumatic disease suggest that active disease increases the risk of adverse events. These patients should hopefully defer pregnancy if possible, use suitable contraception, and be treated aggressively: when disease has been inactive for approximately 6 months, they should be reassessed.[5] Even in RA, disease activity during pregnancy is associated with a small increase in the risk of lower birth weight and pre-term delivery.[6]

### Medication Review

If disease is inactive and there is no indication of severe damage, it is appropriate to assess the patient's present medical regimen. When current medications are contraindicated for use in pregnancy, one option is to taper and discontinue the current medications, allowing an appropriate period of time for high-risk medications to leave the system and for disease to demonstrate stability. The other option is to change to permissible medications and observe for stability on the new regimen.

### Assessment of Autoantibodies

Assessment of autoantibodies helps determine the type and frequency of pregnancy monitoring, the need for potential additional therapy, and to inform both physician and patient regarding risk. Every patient with SLE and patients who have an adverse obstetric history or history of thrombosis should be evaluated for the presence of anti-phospholipid antibodies (aPL). Patients with SLE, RA, undifferentiated connective tissue disease (UCTD), and Sjögren's syndrome should be evaluated for the presence of anti-Ro/SS-A and La/SS-B antibodies.

### Counseling

The full reproductive spectrum from fertility through lactation should be reviewed during the preconception visit. Education should include the risks of pregnancy for the individual patient given her particular clinical profile and is based on damage, disease activity, renal function, aPL, anti-Ro/SS-A and La/SS-B, and medications. Each patient and her partner need to understand the risk to her health, the anticipated pregnancy outcome, and the potential risk to offspring (most commonly pre-term birth or small size for dates). The necessary follow-up and monitoring during pregnancy should be considered, and assure neonatal supportive care if complications develop. Long-term outcomes of children born to mothers with rheumatic disease have received recent attention. Children of both SLE and antiphospholipid syndrome (APS) patients are thought to have a slightly increased risk for developmental disability, thus these children should be monitored accordingly.[7]

## SYSTEMIC LUPUS ERYTHEMATOSUS

**KEY POINTS**

**There is a higher risk of pre-eclampsia, pre-term delivery, fetal loss, and low birth weight infants in SLE patients.**

**SLE can flare up during pregnancy especially in patients with pre-existing renal disease and highly active disease at the time of conception.**

**Anti-malarial medications should be continued during SLE pregnancy; prednisone and prednisolone may be used when necessary, as may azathioprine, cyclosporine, and tacrolimus.**

SLE has its peak incidence in women in their reproductive years, thus co-existing pregnancy in this patient population

is a frequent occurrence. Fertility is generally unimpaired in SLE patients in the absence of severe disease activity or history of cyclophosphamide administration.

## Maternal Outcomes

For many years it was thought that most patients with SLE would worsen during pregnancy, and patients were counseled against becoming pregnant. Recent advances in management and a better understanding of SLE pregnancy has rendered this approach archaic. At present, the majority of women with SLE can anticipate successful pregnancies resulting in a healthy baby. Nonetheless, patients can have flare ups during pregnancy and do experience a higher incidence of pregnancy-related complications. The data on whether SLE significantly worsens during pregnancy or remains stable are conflicting.[8,9] Conflicting results reflect the lack of uniformity in definition of disease flare, differing patient populations, lack of control groups, and varied medication use. Most agree that patients with active disease in the 6 months before conception are at greatest risk for flare during pregnancy. The overall flare rate in patients with active disease in the preconception is estimated at 60%, whereas pregnancy flare rates may be as low as 10% in those with quiescent disease.[10,11]

Women with SLE have a two to fourfold increase in the rate of pregnancy complications. Pre-eclampsia will develop in 25% of women with SLE during pregnancy.[12] Distinguishing a lupus flare from pre-eclampsia is challenging. In general, one expects laboratory and clinical evidence suggesting active disease in a lupus flare, whereas pre-eclampsia is more likely associated with stable disease parameters and an acellular urine despite presence of proteinuria (Table 39-1). Differentiation is important because pre-eclampsia is managed with expectant delivery, whereas lupus flares are managed with medication. In reality, management often includes treatment for both because differentiation may be impossible and disease flare and pre-eclampsia may coexist. In addition to the higher rate of pre-eclampsia, one-third of pregnancies in SLE patients are complicated by pre-term birth, and one-third are delivered by Cesarean section.[13]

## Fetal and Neonatal Outcomes

Fetal loss rate in SLE pregnancies, as manifested by combined miscarriage and still-birth rates, approaches 20%. Although miscarriage rates are not significantly higher than in the general population, the rates of still-birth are significantly increased.[14] Premature delivery, active disease (particularly nephritis), and medication use in SLE pregnancies may contribute to the increased risk of intrauterine growth restriction (IUGR), lower birth weight, and pre-eclampsia.[15,16] Examination of placentas in SLE pregnancies suggests that placental vasculopathy, with or without the presence of aPL, may play an important role.[17] Patients with anti-Ro/SS-A and anti-La/SS-B antibodies are at risk for giving birth to children with neonatal lupus and congenital complete heart block.[18]

## Management

Patients with SLE should be co-managed by a rheumatologist and a maternal-fetal medicine physician. Before pregnancy, patients should have a baseline evaluation including history, physical examination, and laboratory testing as summarized in Table 39-2. Patients should be maintained on antimalarial medication throughout pregnancy because studies suggest benefits for mother and neonate.[19] Patients with active renal disease, central nervous system disease, recent cerebrovascular accident, or PAH should be counseled against pregnancy. In patients with aPL or those who have other risk factors for pre-eclampsia, low-dose aspirin should be prescribed. Those with coexisting APS are managed as outlined below. Patients should have well-controlled disease on low-risk medications for six months prior to attempting conception. Disease flares are managed with nonfluorinated glucocorticoids and, if necessary, the introduction of immunosuppressive agents compatible with pregnancy.

**TABLE 39-1** Differentiating Systemic Lupus Erythematosus Flare during Pregnancy From Pre-eclampsia

| Systemic Lupus Erythematosus Flare | Pre-eclampsia |
|---|---|
| Low white blood cell count | Normal to high white blood cell count |
| Occasional thrombocytopenia | Frequent thrombocytopenia |
| Normal liver function tests | Elevated liver function tests |
| Elevated blood pressure | Elevated blood pressure |
| Proteinuria | Proteinuria |
| Cellular urine with red blood cells and casts | Acellular urine |
| Normal uric acid | Elevated uric acid |
| Low complement levels | Normal to elevated complement levels |
| Increase anti-dsDNA levels | No change in dsDNA levels |

**TABLE 39-2** Pre-pregnancy Work-Up for Systemic Lupus Erythematosus

| |
|---|
| Complete blood count with differential and platelets |
| Complete metabolic panel |
| Urinalysis including microscopic analysis |
| Spot protein/creatinine urine ratio or 24-hour urine collection for protein* |
| Complement levels (C3, C4) |
| Anti-dsDNA level |
| Anti-Ro/SS-A and Anti-La/SS-B antibodies |
| Anti-phospholipid antibodies: Anti-cardiolipin antibodies, anti-beta2 glycoprotein I antibodies, and lupus anti-coagulant |
| Uric acid levels |

*As appropriate.

## MIXED CONNECTIVE TISSUE DISEASE AND UNDIFFERENTIATED CONNECTIVE TISSUE DISEASE

**KEY POINTS**

**Patients with mixed connective tissue disease or undifferentiated connective tissue disease are likely to have uncomplicated pregnancies unless accompanied by PAH or progression to more well-defined systemic rheumatic disease.**

The mixed connective tissue disease (MCTD) has many clinical features in common with SLE. Undifferentiated connective tissue disease (UCTD) is terminology applied to patients who have autoantibodies and clinical findings suggestive of rheumatologic disease but who cannot be classified with a specific disorder. Fertility is not reduced in women with MCTD or UCTD.

### Maternal Outcomes

Limited data are available on pregnancy outcomes in women with these disorders. In a series of ten patients with MCTD, three had flares during pregnancy.[20] Flares included proteinuria, myositis, synovitis, and serositis. There are case reports of PAH appearing in pregnant MCTD patients[21]; thus pre-pregnancy echocardiogram screening for PAH should be considered. In 25 reported UCTD pregnancies, six patients had flares and symptoms meeting criteria for a new SLE diagnosis developed in one patient.[22]

### Fetal and Neonatal Outcomes

There is no increase in fetal loss in women with MCTD[23] although there are rare case reports of skeletal abnormalities in offspring of MCTD mothers.[24] In general, patients with MCTD and UCTD have good pregnancy outcomes, although they should be monitored for disease flares and progression to other systemic rheumatic diseases.

## SJÖGREN'S SYNDROME

**KEY POINTS**

**Mothers who are Anti-Ro/SS-A and anti-La/SS-B antibody-positive are recommended to have serial fetal echocardiograms to assess for development of congenital complete heart block; hydroxychloroquine may have a protective effect against congenital complete heart block.**

Although there are no reports of diminished fertility in patients with Sjögren's syndrome, some women experience dyspareunia because of vaginal dryness related to exocrine dysfunction in their underlying disease.

### Maternal Outcomes

Case reports exist of new onset renal disease and pericarditis in women with Sjögren's syndrome during pregnancy,[25] but no large-scale studies exist that document a pregnancy-associated increase in disease activity.

### Fetal and Neonatal Outcomes

Small series have suggested an increased risk of fetal loss in women with Sjögren's syndrome,[26] but larger studies have not substantiated this finding.[27] Sixty percent of patients with Sjögren's syndrome have anti-Ro/SS-A and anti-La/SS-B antibodies. These antibodies confer risk for the development of congenital complete heart block (CHB) (2%) and neonatal lupus erythematosus manifestations, including reversible thrombocytopenia, transaminitis, and photosensitive rash in their offspring (7% to 16%).[18]

### Management

Antibody-positive women should undergo screening fetal echocardiograms between 18 and 28 weeks of pregnancy to monitor for the development of CHB. Fluorinated glucocorticoids and intravenous immunoglobulin (IVIG) have been used to prevent development of CHB when first or second degree heart block is detected, but controlled studies have failed to demonstrate efficacy. Preliminary data suggest that hydroxychloroquine (HCQ) may reduce CHB risk.[28]

## ANTI-PHOSPHOLIPID ANTIBODY

**KEY POINTS**

**Presence of lupus anticoagulant is the most important risk factor for adverse pregnancy outcome in aPL-positive women.**

**Standard prophylactic therapy for obstetric anti-phospholipid syndrome is a combination of low-dose aspirin and low-dose heparin (low-molecular-weight heparin or unfractionated heparin).**

The presence of anti-phospholipid antibody (aPL) is a risk factor for pregnancy loss and other adverse pregnancy outcomes, especially when present in association with SLE. Clinical criteria for obstetric anti-phospholipid syndrome (OB-APS) include pregnancy loss (three or more consecutive losses at less than 10 weeks of gestation or one or more losses on or after 10 weeks of gestation) or delivery at less than 34 weeks of gestation because of pre-eclampsia, IUGR, or fetal distress. Laboratory criteria include persistent lupus anticoagulant (LAC) or moderate to high titer IgG or IgM isotypes of anti-cardiolipin (aCL) or anti-beta-2-glycoprotein I (aβ2GPI) antibodies.[29] Importantly, other causes of pregnancy loss must be ruled out with appropriate reproductive medicine evaluation. When considering a diagnosis of OB-APS, all three criteria aPL (LAC, aCL, and aβ2GPI) should be tested. The usefulness of alternative (non-criteria) aPL testing is uncertain.

The potential effect of aPL on fertility has been controversial, with the concern that aPL may interfere with implantation, particularly after IVF. However, the Practice Committee of the American Society for Reproductive Medicine has released guidelines based on extensive literature review stating that there is no indication to check aPL as

part of a fertility work-up, or to treat aPL-positive women for the purpose of improving IVF cycle outcome.[30]

### Maternal Outcomes

Maternal complications associated with OB-APS include pregnancy loss, pre-eclampsia, eclampsia, and HELLP syndrome. Anti-phospholipid antibody associated with HELLP syndrome generally occurs early (at 28 to 36 weeks), with hepatic infarction in one-third of cases and frequent progression to other thrombotic complications.[31] Other maternal complications include thrombosis (including catastrophic APS) and severe third-trimester thrombocytopenia.

### Fetal and Neonatal Outcomes

The most frequent neonatal complications are premature birth and IUGR. Premature births are more common in patients who have both APS and SLE. In primary APS pregnancies, risk factors for poor neonatal outcome are similar to predictors for adverse pregnancy outcomes overall, and include LAC, triple antibody positivity (defined as presence of LAC, aCL, and aβ2GPI), and history of vascular thrombosis. Patients with previous pregnancy morbidity alone without history of thrombotic manifestations may have a more favorable neonatal outcome.[32] Transplacental passage of anti-cardiolipin antibody has been documented, but thrombosis in the fetus or neonate is rare. Neonatal APS has been reported in less than 20 infants, and many infants had additional thrombotic risk factors, such as indwelling catheters.[33]

### Management

Effective management of the aPL-positive patient during pregnancy requires accurate assessment of risk for adverse pregnancy outcome. In the prospective multicenter PROMISSE (Predictors of Pregnancy Outcome: Biomarkers in Anti-phospholipid Syndrome and Systemic Lupus Erythematosus) study, LAC was identified as the most important risk factor for adverse pregnancy outcome in aPL-positive women. Multivariate analysis showed relative risk for adverse pregnancy outcome with LAC to be 12.33.[34] Other PROMISSE risk factors included younger age, history of thrombosis, and SLE. Importantly, aCL and aβ2GPI status were not independently associated with adverse pregnancy outcome.[34] Triple aPL positivity has also been suggested as an important risk factor in other cohorts,[35] and presence of low complement levels may also be associated with increased risk.[36]

A 1992 prospective study by Cowchock et al. showed that low-dose heparin plus low-dose aspirin is equal in efficacy to prior therapy with corticosteroids plus low-dose aspirin, with fewer side effects.[37] This combination remains the standard of care, with either low-molecular-weight heparin (LMWH) or unfractionated heparin (UF). Meta-analyses of treatment trials confirm the benefit of combination therapy; however, controversy continues regarding the details of the efficacy of this therapy. One analysis of five studies with 334 primary APS patients suggested success rates of 75% vs. 56% for combination therapy versus low dose aspirin alone[38]; another meta-analysis found combination therapy to be effective for early but not late losses, and found UF, but not LMWH, to improve outcomes.[39] Second-line therapy for treatment failure is usually the addition of IVIG based on case reports, although randomized treatment trials do not support its benefit.[40] Future therapies based on murine models may include complement[41] or tumor necrosis factor (TNF) inhibitors.[42] No strong data currently exist to support the treatment of obstetric patients with asymptomatic aPL antibodies, but low-dose aspirin is often used empirically for patients with high-risk aPL profiles. Low-dose aspirin seems especially reasonable for patients with additional risk factors for pre-eclampsia, including concomitant SLE, hypertension, or renal insufficiency. Patients with previous thrombosis require therapeutic heparin throughout pregnancy, with a change from warfarin either preconception or before six weeks' gestation, to avoid warfarin embryopathy. Heparin dosing usually requires adjustment later in pregnancy because of increased clearance, and LMWH is frequently changed to UF near term because of its shorter half-life. Fetal monitoring with nonstress tests, Doppler studies, or serial ultrasound is routine in the third trimester. Postpartum anticoagulation should be continued for 6 to 12 weeks. Recommendations for long-term thrombosis prophylaxis in patients with OB-APS without a history of thrombosis are lacking, although one large observational cohort study reported an increased risk for subsequent deep vein thrombosis and stroke in these women.[43]

## INFLAMMATORY ARTHRITIS

**KEY POINTS**

- **RA tends to improve during pregnancy.**
- **Active RA during pregnancy can result in lower birth weight infants.**
- **Preconception planning for inflammatory arthritis patients may require medication adjustments: anti-malarials and sulfasalazine can potentially be continued, methotrexate and leflunomide must be discontinued, and recent data suggest TNF inhibitors may be continued if necessary.**

### Rheumatoid Arthritis

Rheumatologists are frequently required to manage RA during pregnancy and, less commonly, to manage pregnancy in women with psoriatic arthritis (PsA) and the spondyloarthropathies (SpA). Smaller family size has been reported in women with RA diagnosed before childbearing.[44,45] Decreased family size is likely multifactorial and may include delays in conception because of disease activity or medication adjustment. Reduced fertility does not seem to be related to ovarian function because anti-Müllerian hormone levels (a marker of ovarian reserve) are normal.[46]

#### Maternal Outcomes

Clinically meaningful remission in RA during pregnancy may be difficult to define, in part because inflammatory markers, including ESR and c-reactive protein (CRP), are elevated in healthy pregnancies and do not provide a good reflection of disease activity. Hench first noted in the 1930s

that many RA patients improve during pregnancy.[47] Although early reports suggest approximately 70% of RA patients enter remission during pregnancy,[48] a 2008 study that used the Disease Activity Scale (DAS) 28 found that only 48% of RA patients improved.[49] Patients who are anti-cyclic citrullinated peptide (CCP) antibody and rheumatoid factor (RF) negative are more likely to remit.[50]

### Fetal and Neonatal Outcomes

RA does not increase the rate of fetal loss during pregnancy.[51] Even after controlling for medication use, women with active RA during pregnancy are found to be at risk for giving birth to small for gestational age infants.[6,52] Minimizing disease activity during pregnancy appears to be important for optimal fetal outcome.

## Psoriatic Arthritis and Ankylosing Spondylitis

Case series suggest that remission rates for PsA are similar to those for RA.[53] Results are more disparate for pregnancy in spondyloarthropathies. One survey of 649 women with ankylosing spondylitis (AS) found that roughly one-third of patients worsened, one-third stayed the same, and one-third improved during pregnancy.[53,54] In another case-controlled study of 35 pregnancies in mothers with AS, 51% of patients reported decreased pain.[55] Cesarean section rates may be as high as 58% in the spondyloarthropathies, with a reported miscarriage rate of 15% and normal rates of term delivery.[53,54]

## Management

Teratogenic medications such as methotrexate and leflunomide must be discontinued before pregnancy; current evidence suggests that other medications such as anti-malarials and sulfasalazine may be continued. Recent evidence suggests that TNF inhibitors may be continued during pregnancy through the second trimester in women with active disease. Nonsteroidal anti-inflammatory drugs (NSAIDs) and glucocorticoids may be used sparingly during pregnancy. Evaluation of cervical spine stability and hip range of motion is suggested before delivery.

# INFLAMMATORY MYOSITIS

**KEY POINTS**

- **Quiescent disease at conception is associated with better pregnancy outcomes for idiopathic inflammatory myopathy patients.**
- **Corticosteroids, intravenous immunoglobulin and azathioprine are useful for idiopathic inflammatory myopathy, flares during pregnancy.**

Idiopathic inflammatory myopathies (IIM) include polymyositis (PM), dermatomyositis (DM), juvenile myositis (JM), and inclusion body myositis (IBM). Because the age of onset is bimodal, either in childhood or older adulthood, it is uncommon for patients to have pregnancies after the diagnosis of adult-onset myositis, and data are limited. One series found myositis developed in only 14% of patients before or during the childbearing years[56]; another recent series reported 8 in 51 patients with pregnancies following diagnosis.[57] There are no data on fertility in patients with IIM.

## Maternal Outcomes

Pregnancies have been reported during both quiescent and active periods of disease, and a number of reports have described new onset disease during or immediately after pregnancy.[56,58] New disease onset during pregnancy is often acute and severe, and rhabdomyolysis and myoglobinuria have been reported.[58] Risk of flare during pregnancy for patients in remission before conception is low.[57] Although disease with onset during pregnancy has a more severe course, maternal outcome is good overall for patients with IIM, and maternal mortality is rare.

## Fetal and Neonatal Outcomes

Neonatal outcomes for patients with pre-existing disease who are in remission at time of conception are best, with no increased risk for fetal loss. Active disease early in the pregnancy has an adverse effect on fetal and neonatal outcomes, whereas flare later in pregnancy does not. Neonatal outcomes are worst for patients with new-onset disease during pregnancy, with only a 38% survival rate.[59,60] In addition to fetal loss, prematurity, and IUGR, other uncommon fetal outcomes have been reported. Two infants with elevated creatine kinase (CK) levels at birth were born to mothers with IIM.[61] Massive perivillous fibrin deposition of the placenta has also been reported, a pathology finding associated with clinical evidence of placental insufficiency and poor fetal outcomes.[56,58,62]

## Management

Patients with IIM are most likely to have successful pregnancies if disease is quiescent before conception. No evidence supports prophylactic corticosteroid treatment, but careful follow-up with prompt treatment of even mild disease flares may improve pregnancy outcome. IVIG has been used successfully with disease onset in the first trimester.[63] Azathioprine may be considered, either alone or in combination with IVIG.

# SYSTEMIC SCLEROSIS

**KEY POINTS**

- **Systemic sclerosis patients with active renal disease, PAH, or significant cardiac compromise should avoid pregnancy because of high risk for poor maternal outcome.**
- **Systemic sclerosis patients with early diffuse disease should defer pregnancy due to a higher risk of scleroderma renal crisis.**

Systemic sclerosis (SSc) is an uncommon disease with a predilection for women during the fifth to sixth decade of life; as a result, there is limited information on this disorder during pregnancy. However, while more women extend

childbearing into their forties, pregnancy issues in SSc become more relevant. Data on whether SSc impacts fertility are conflicting. One retrospective study reports a greater than twofold incidence of infertility before diagnosis,[64] but another study did not find decreased fertility.[65]

### Maternal Outcomes

Raynaud's syndrome in SSc pregnancy generally improves because of increased blood flow to the periphery, whereas gastroesophageal reflux often worsens because of diaphragmatic relaxation. Skin disease does not progress.[66] Patients with early diffuse SSc and active skin thickening may have a higher risk of scleroderma renal crisis during pregnancy.[67] Management of renal crisis during pregnancy is challenging because angiotensin-converting enzyme (ACE)-inhibitors and angiotensin receptor blockers (ARBs) are contraindicated; however, when life-threatening disease occurs, these medications should be used. Scleroderma renal crisis may be difficult to differentiate from pre-eclampsia. Patients with pre-existing PAH are at very high risk for serious pregnancy complications: fluid shifts during pregnancy and especially during delivery may lead to right heart failure and, in some instances, death.[3] These patients should be counseled to avoid pregnancy.

### Fetal Outcomes

Retrospective studies reveal a twofold increase in spontaneous abortion rate in women who are subsequently diagnosed with SSc,[68] and women with SSc have higher rates of preterm delivery. Other reported complications include IUGR and low-birthweight infants.[66]

### Management

Given the potential for renal crisis, SSc patients should be followed by a rheumatologist and a maternal-fetal medicine specialist. Patients with PAH should be counseled about the high risk of maternal morbidity and mortality. Those with pre-existing renal disease should have their disease well-controlled on medications compatible with pregnancy.

## VASCULITIS

**KEY POINTS**

- **Pregnancy outcome in Takayasu's arteritis patients is largely determined by the presence of hypertension and pre-existing vascular damage. Aortic valve disease and the presence of aortic or renal aneurism are contraindications to becoming pregnant.**
- **Patients with medium- and small-vessel vasculitides are likely to have safe and successful pregnancies if conception is during a period of disease remission.**
- **Pregnancy in Behçet's disease has a variable effect on disease activity, but overall, fetal/neonatal outcomes are good.**
- **Medical management for patients with vasculitis during pregnancy may involve corticosteroids, azathioprine, IVIG, and rarely, cyclophosphamide in the third trimester for life-threatening disease.**

There are a limited number of reported cases of pregnancy in systemic vasculitis, resulting from both the older age of onset and male predominance. The available literature suggests active disease at the time of conception or new disease onset during pregnancy carries the most serious prognosis for maternal health and pregnancy outcome. Presence of vasculitis activity and end-organ damage may both affect pregnancy outcome. There are no data on fertility in these patients. In general, women who conceive after the diagnosis of any vasculitis report higher rates of pregnancy loss and pre-term delivery.[69] Flares of vasculitis activity during pregnancy vary from 18% to 50%.[69,70] A prospective series reported rates of miscarriage to be 20%; PROM, 33%; and pre-term delivery, 50%.[70]

### Large Vessel Vasculitis: Takayasu's Arteritis

Takayasu's arteritis is unique among the vasculitides in that it most commonly affects young women. Pregnancy complications are usually the result of vascular damage rather than disease activity, and pregnancy and maternal outcomes are optimized in patients with fewer damaged vessels. Risk of hypertension, pre-eclampsia, and IUGR is high, whereas likelihood of relapse of active vasculitis is low. In a large systematic review of 214 pregnancies in Takayasu's patients, pre-eclampsia occurred in 45% and pre-term delivery occurred in 16% of pregnancies.[71] Although pregnancy did not affect disease activity, pre-existing aortic valve disease or aortic or renal artery aneurysm conferred high risk for maternal mortality.[71] Another case series reported serious maternal complications of congestive heart failure, renal insufficiency, and cerebral hemorrhage. Neonatal effects included low birth weight, premature delivery, and IUGR in as many as 40% of newborns, but favorable outcome overall in 85%.[72]

Risk of complications such as cerebral hemorrhage or infarction in patients with Takayasu's arteritis is greatest at delivery because of fluctuations in regional blood flow. Monitoring of central aortic blood pressure is recommended for patients with severe vascular disease, with cautious use of epidural anesthesia to circumvent blood pressure vacillations. Active disease is unlikely and so most patients will not require immunosuppressive therapy.

### Medium Vessel Vasculitis: Polyarteritis Nodosa

The earliest reports of polyarteritis nodosa (PAN) in pregnancy suggested high rates of maternal mortality. New onset disease during pregnancy mimicked pre-eclampsia, and diagnosis was delayed in most cases.[73] Recent reports of pregnancies in established disease suggest better outcomes during periods of remission.[74] Fetal outcome overall is good. Because the new onset disease is most often in the third trimester or postpartum period, the risk to the pregnancy is that of prematurity and low birth weight rather than fetal loss. Infants with transient cutaneous vasculitis have been reported.[75] Management includes use of corticosteroid and immunosuppressive medications.

### ANCA-Associated Vasculitis

In granulomatosis with polyangiitis (GPA), there is a 25% relapse rate during pregnancy, but a high rate of successful

pregnancy outcome. As with PAN, adverse outcome is more likely in those with active or new manifestation of disease during pregnancy. Because most cases of new diagnoses have been in the third trimester, most of these pregnancies result in live-born births but pre-term deliveries. Quiescent disease at conception yields better outcomes.[76,77] Successful case reports describe the use of IVIG, azathioprine, and plasma exchange. Rarely, critically ill patients have been treated with cyclophosphamide in the second or third trimester with good neonatal outcome.[76] Severe subglottic stenosis may complicate delivery and require temporary tracheotomy to protect the airway.

Eosinophilic granulomatosis with polyangiitis (EGPA) (Churg-Strauss syndrome) case reports suggest maternal morbidity to be lower than in PAN.[78] Microscopic polyangiitis in pregnancy has rarely been reported, including a neonate with (transplacental) myeloperoxidase (MPO) antibodies, pulmonary hemorrhage, and renal disease.[79]

### Behçet's Disease

There are contradictory reports of pregnancy effects on disease activity in patients with Behçet's disease. A recent literature review including 220 pregnancies found improved disease activity in 63% of cases and relapse in 28% of cases.[80] Necrotizing neutrophilic vasculitis in two placentas has been described.[81] Pregnancy outcome overall is good, with a miscarriage rate of 20%.[82] Infants with pustulonecrotic skin lesions have been described,[83] and there is a potential increased risk of thrombosis.

## MEDICATIONS DURING PREGNANCY AND BREASTFEEDING

**KEY POINTS**

- **NSAIDs may be associated with early fetal loss, and their use should be minimized during early pregnancy. NSAIDs should be discontinued after 30 weeks' gestation because of the risk of premature closure of the ductus arteriosus.**
- **Prednisone and prednisolone are the preferred corticosteroids for use during pregnancy because low amounts are transferred across the placenta; fluorinated steroids such as dexamethasone and betamethasone are reserved for use when treatment of the fetus is desired.**
- **Hydroxychloroquine, sulfasalazine, azathioprine, 6-mercaptopurine, cyclosporine, tacrolimus, and IVIG are compatible with pregnancy.**
- **TNF inhibitors can be used when needed to control active inflammatory arthritis. They should be discontinued after the second trimester if possible circumvent immunosuppression in the newborn. Avoid live vaccines for six months in infants exposed to biologics during pregnancy.**

Medication management during pregnancy and lactation is challenging. Potential risks to the developing fetus and newborn must be weighed against the benefits of disease control. Limited information exists regarding drug safety in pregnancy. The current Food and Drug Administration (FDA) labeling system is imperfect because it utilizes a graded system of A, B, C, D, and X, which incorrectly implies an increased risk with ascending letter grade. A soon-to-be-released revision of the FDA labeling system will include three sections for each drug: a risk summary, clinical considerations, and a data section. When assessing any medication, risk must be measured against the reported background congenital anomaly rate of approximately 3%. Although benefits of breastfeeding extend to both the mother and the infant, medication use during the postpartum period can complicate lactation. Drugs are transferred to breast milk by diffusion: nonprotein bound, low-molecular-weight, nonionized, and lipid-soluble medications are most likely to enter breast milk.[84] Below is a discussion on the safety of the more commonly used medications for rheumatologic disorders in pregnancy and lactation (Table 39-3).

Ideally, medications should be adjusted before conception, but inadvertent exposure to teratogenic medications does occur. If this happens, the patient should be provided with information on the potential risks of exposure, and referred to appropriate registries such as Organization of Teratology Information Specialists, or OTIS (http://www.mothertobaby.org/). If available, high-resolution fetal ultrasound should be performed to assess for detectable anomaly.

### Aspirin, Nonsteroidal Anti-inflammatory Medications, and Cyclooxygenase-2 Inhibitors

High dose aspirin and NSAIDs are teratogenic in animals, but congenital anomalies have not been reported in humans.[85] NSAIDs can cause premature closure of the ductus arteriosus in the third trimester and should be discontinued by 30 weeks' gestation. Both NSAIDs and cyclooxygenase-2 (COX-2) inhibitors can potentially interfere with implantation and ovulation, and should be avoided during a conception cycle.[86] There are conflicting data as to whether NSAIDs and COX-2 inhibitors increase risk of spontaneous abortion during the first trimester.[87,88] Although findings are inconclusive, it seems reasonable to minimize the use of these medications during pregnancy. NSAIDs cross into breast milk at very low concentration; thus these medications are thought to be compatible with nursing. Mothers of jaundiced infants should avoid those medications metabolized by the liver, and all NSAIDs should be avoided in lactating mothers whose infants have thrombocytopenia.

### Glucocorticoids

The nonfluorinated glucocorticoids prednisone and prednisolone, which are typically used in the management of rheumatologic diseases, cross the placenta in low concentrations. In contrast, fluorinated glucocorticoids such as betamethasone readily cross the placenta to reach the developing fetus.[89] Recent evidence suggests that there is no increased rate of congenital anomalies after in utero glucocorticoid exposure.[90] Glucocorticoid use throughout pregnancy increases risk of pre-term delivery, small-for-gestational age infants, maternal hypertension, and gestational diabetes. Prednisone and prednisolone cross into breast milk in very low concentrations[91] and can be used in lactating women. When the dose is greater than 20 mg a day, avoiding breastfeeding within 4 hours of drug administration is recommended.

**TABLE 39-3** Risks of Rheumatic Disease Medications during Pregnancy and Lactation

| Drug | Maternal | Fetal | Lactation |
|---|---|---|---|
| ***Minimal Risk*** | | | |
| Hydroxychloroquine | None | None | Compatible |
| Sulfasalazine | Additional folic acid required as absorption is decreased | None | Compatible-one case of bloody diarrhea reported in neonate |
| IVIG | Risk of hepatitis C | Risk of hepatitis C | Compatible |
| Unfractionated heparin | Bleeding | None | Compatible |
| LMW heparin | Bleeding | None | Compatible |
| Aspirin (low dose) | Bleeding | None | Compatible |
| ***Low to Moderate Risk*** | | | |
| NSAIDs | Interferes with ovulation and implantation, possible increase in first trimester pregnancy losses | Safe; discontinue after 30 weeks of gestation because of increased risk of premature closure of the ductus arteriosus | Compatible but avoid NSAIDs with long half-life and enterohepatic circulation |
| Prednisone and Prednisolone | PROM, gestational diabetes, hypertension | Possible<br>No increase in congenital anomalies | Compatible but at dosing greater than 20 mg a day, discard breast milk for 4 hours after dose |
| Azathioprine<br>6-Mercaptopurine<br>Cyclosporine A<br>Tacrolimus | None<br>None<br>Renal Insufficiency<br>None | Transplant and IBD literature endorse the safety of these immunosuppressives during pregnancy. All increase the risk of PROM, SGA, IUGR | Low risk<br>Low risk<br>Low risk<br>Low risk |
| Etanercept<br>Adalimumab<br>Infliximab<br>Golimumab<br>Certolizumab | None<br>None<br>None<br>None<br>None | | TNF inhibitors: Low concentration in breast milk- low risk |
| Colchicine | None | Limited studies in FMF suggest that this medication can be used during pregnancy | |
| ***High Risk*** | | | |
| Methotrexate | | Embryotoxic and Teratogenic | Avoid |
| Leflunomide | | Congenital anomalies reported | Avoid |
| Cyclophosphamide | Maternal infection | Teratogenic | Avoid |
| Mycophenolate Mofetil | | Congenital anomalies reported | Avoid |
| Warfarin | Bleeding | Teratogenic | Avoid |
| ***Unknown Risk*** | | | |
| Rituximab | | | Avoid |
| Abatacept | | | Avoid |
| Tocilizumab | | | Avoid |
| Anakinra | | | Avoid |
| Belimumab | | | Avoid |
| Tofacitinib | | | Avoid |

IBD, Inflammatory bowel disease; IVIG, intravenous immunoglobulin; IUGR, intrauterine growth retardation; FMF, familial Mediterranean fever; LMW, low-molecular-weight; NSAIDS, nonsteroidal anti-inflammatory drugs; PROM, premature rupture of the membranes; SGA, small for gestational age newborns; TNF, tumor necrosis factor.

Modified from Bermas, BL: The medical management of the rheumatology patient during pregnancy in *Contraception and pregnancy in patients with rheumatic disease*. Springer New York, 2014, p. 275.

## Antimalarial Agents

Chorioretinotoxicity has been reported in rodent offspring after in-utero exposure to anti-malarials, and one case report suggests hearing issues in human offspring after chloroquine therapy during pregnancy.[92] However, multiple case series have not demonstrated an increased risk of teratogenicity in human pregnancy.[93] A 2002 survey of North American rheumatologists revealed that 69% prescribed anti-malarials during pregnancy.[94] Importantly, no ocular toxicity was found on examination of 588 neonates exposed to these medications in utero.[95] Anti-malarials cross into breast milk at low concentration, but exposed neonates showed no ocular toxicity.[96] These medications are considered to be compatible with nursing.

## Sulfasalazine

Although sulfasalazine and its metabolites do cross the placenta, large case series have not shown evidence for teratogenicity.[97] Sulfasalazine interferes with folic acid absorption, and thus pregnant women on this medication should take

additional folic acid. Men on this medication should discontinue the drug 3 months before conception to avoid azoospermia. Sulfasalazine appears in breast milk in significant concentrations. A single case of bloody diarrhea in a breast-fed infant has been reported,[98] but this medication is considered compatible with nursing. Because the active metabolite of sulfasalazine can displace bilirubin, women nursing premature infants, infants with hyperbilirubinemia, or infants deficient in glucose-6-phosphate dehydrogenase should avoid this medication.

## Immunosuppressive Agents

Methotrexate is both teratogenic and abortogenic and is contraindicated during pregnancy. In humans, methotrexate exposure during pregnancy particularly between 6 and 8 weeks' gestation can lead to craniofacial and limb malformations as well as significant developmental delays.[99] Although no definitive data suggest that men taking this medication are at increased risk for children with congenital anomalies, it is recommended that men discontinue methotrexate 3 months before conception to allow for a cycle of spermatogenesis. In women, methotrexate should be discontinued three months prior to conception. Limited data suggest that methotrexate is poorly transmitted into breast milk; however, current recommendations are to avoid use in lactating women.

Leflunomide is considered a potent teratogen in rodents.[100] Although recent studies suggest early exposure results in few anomalies in humans,[101] current recommendations are to either stop this medication 2 years before conception or to treat the patient with a cholestyramine wash-out to remove active metabolites in anticipation of pregnancy. There are no data as to whether leflunomide crosses into breast milk in significant concentrations. However, given the long half-life, leflunomide should be avoided in lactating women.

Although azathioprine and 6-mercaptopurine (6-MP) are category D drugs, large transplant registries have followed thousands of treated pregnancies and do not demonstrate an increased rate of congenital anomalies in exposed infants.[102] Minimal levels are found in breast milk[103]; thus use of these medications in nursing mothers of full-term infants is low risk, although testing for thiopurine S-methyltransferase (TPMT) levels in the newborn may be considered. Cyclosporine does not carry an increased risk of congenital anomalies. Although low levels of this medication have been found in breast milk, a single breast-fed infant was found to have a therapeutic level after nursing.[104] Tacrolimus has been used in the management of lupus nephritis, and this medication is considered compatible with pregnancy.[105] Little tacrolimus is transferred into breast milk and thus breastfeeding may be low risk for the neonate.[106] Mycophenolate mofetil, although a cornerstone of lupus nephritis management, has been associated with patterns of congenital anomalies and is contraindicated during pregnancy and breastfeeding.[107] Cyclophosphamide is extremely teratogenic and is contraindicated during pregnancy, although there are rare successful case reports of use during the third trimester for the management of vasculitis.[108] It is contraindicated in nursing women.

## Intravenous Immunoglobulin

There are limited data on the safety of IVIG during pregnancy, but no cases of congenital anomalies have been reported[109]; it is compatible with pregnancy and lactation.

## Tumor Necrosis Factor Inhibitors

Most TNF inhibitors are not actively transported through the placenta until 15 weeks' gestation, when elevated levels in cord blood can be found. A concerning report in 2009 described a clustering of congenital anomalies suggestive of VACTERL syndrome (vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula, esophageal atresia, renal anomalies, and limb dysplasia) in infants exposed to TNF inhibitors in utero.[110] Although subsequent analysis did not support an association,[111] this report informed decision-making for many rheumatologists who avoided prescribing these medications during pregnancy. PEGylated forms (those linked to a polyethylene glycol, or PEG, chain) cross the placenta in very limited amounts and thus may be preferred for use during pregnancy.[112] A 3-month old infant of a mother treated with infliximab throughout pregnancy died of disseminated infection after bacille-Calmette-Guérin (BCG) immunization,[113] thus current recommendations are to discontinue these medications by the third trimester of pregnancy and to avoid immunizations with live vaccines for 6 months in exposed infants. Transfer of TNF inhibitors into breast milk is minimal.[114]

## Other Biologic Agents

Limited information exists on the safety of other biologic medications during pregnancy. One large series of 153 pregnancies in rituximab-exposed fetuses demonstrated that the congenital malformation rate was similar to the background rate.[115] Given that little IgG crosses the placenta before 12 weeks of gestation, it seems unlikely that significant amounts of biologic agents would reach the developing fetus if medication is discontinued before conception. There are varied recommendations by manufacturers as to when these medications should be discontinued prior to pregnancy, with ranges from a few months (belimumab, abatacept) to a year (rituximab).

## Other Medications

Anticoagulation is the mainstay of therapy for the management of APS during pregnancy. Although warfarin is contraindicated during pregnancy because of its teratogenicity, heparin and LMWH are considered compatible with pregnancy and lactation. There is insufficient information on the newer anti-coagulants to assess their safety during pregnancy and lactation. Colchicine is rarely used during pregnancy; however, available data suggest that use during pregnancy does not cause congenital anomalies.[116] ACE inhibition and ARBs are contraindicated during pregnancy and lactation because of the risk of oligohydramnios and renal failure in the newborn; transition to another anti-hypertensive in advance of conception is recommended.

# PREGNANCY-RELATED ISSUES FOR RHEUMATIC DISEASE PATIENTS

**KEY POINTS**

- **Contraceptive options should be discussed with all female patients of reproductive age, with recommendations tailored to the individual patient's medical and social situation.**
- **Combined hormonal contraceptives may be used in stable SLE patients but are contraindicated in patients with positive aPL.**
- **Levonorgestrel IUDs or progesterone subdermal implants are good alternatives for most aPL-positive patients.**

## Contraception

Rheumatic disease patients are strongly advised to use contraception to avoid pregnancy if they have severe disease-related damage, active disease, or are taking teratogenic medications. In practice, however, rheumatic disease patients underutilize effective contraception. In a series of 97 SLE patients at risk for pregnancy, 23% had unprotected sex "most of the time."[117] In another series, 55% of those who used contraceptives were using less effective barrier methods, even those on teratogenic medications.[118] Inconsistent contraceptive use may reflect a lack of counseling by physicians.[119] Efforts at formalizing patient education to improve physician and patient awareness of effective contraception include educational materials, the use of institutional quality indicators, and adherence to FDA recommendations.

### Contraceptive Methods

Currently available contraceptives include barrier methods, hormonal contraceptives, intrauterine devices (IUDs), and subdermal implants. In general, long-acting reversible contraceptives such as IUDs or subdermal implants have the greatest efficacy, followed by other hormonal contraceptives; barrier or natural methods of contraception are least effective.

IUDs generally contain either progesterone (levonorgestrel) or copper. They have a low risk of infection for most patients; however, patients treated with immunosuppressive medications have not been specifically studied. Reassuringly, studies show no increased infection risk in women infected with human immunodeficiency virus.[120]

Hormonal contraceptives may be combined estrogen-progesterone or progesterone-only. Combined hormonal contraceptives include the pill, transdermal patch, and vaginal ring. Serious side effects include a three to five times increase in the risk of venous thromboembolism and a two time increase in stroke risk. Common medications, including warfarin and mycophenolate, may interact with these agents. In the past, concern about estrogen-induced flares has limited use of combined oral contraceptives in patients with SLE; however, prospective controlled studies in women with mild or stable disease activity showed no increased risk of flares with combined oral contraceptive (COC) use.[121,122] Oral contraceptives containing the progestin drospirenone may increase potassium levels and should be used with caution in patients with nephritis or on ACE-inhibitors. While the vaginal ring provides equal or lower estrogen levels than the pill, the patch provides 60% greater estrogen levels and may further increase thrombosis risk. Estrogen-containing contraceptives are not advised for use in aPL-positive patients.

Progesterone-only contraceptives include oral and intramuscular forms, IUDs, and the subdermal etonogestrel implant. Prolonged depot medroxyprogesterone acetate (DMPA) may decrease bone density due to inhibition of ovulation: it is best avoided in corticosteroid-treated patients. Progesterone-only contraceptives represent the best option for aPL-positive patients: the risk for thromboembolism is low and they generally decrease menstrual bleeding, a potential benefit for patients on anticoagulation. Emergency contraception is an option for all rheumatic disease patients and includes the copper IUD, prescription progesterone-receptor modulators, and over-the-counter levonorgestrel. Levonorgestrel is effective, convenient, and not contraindicated in patients with thrombophilia or cardiovascular disease.

Contraceptive choice in patients with rheumatic disease is challenging but important. The progesterone IUD or subdermal implant is preferable for most patients. Ultimately, decisions regarding contraceptive method in patients must take into account not only the risk of the method but also the risk of unplanned pregnancy, the ease of use, and the efficacy of each method. See Table 39-4.

## Fertility and Assisted Reproductive Techniques

**KEY POINTS**

- **Measures to preserve fertility in rheumatology patients include use of leuprolide during treatment with cyclophosphamide and embryo or oocyte cryopreservation.**
- **Risk of lupus flare and thrombosis are concerns for SLE and aPL/APS patients undergoing ovarian induction/in vitro fertilization; careful management generally results in successful outcomes.**

Fertility is generally unimpaired by rheumatic diseases, with important exceptions. Patients treated with cyclophosphamide (CYC) are at risk for gonadal failure, especially with older age and greater cumulative dose.[123] Active disease, high-dose corticosteroid, and chronic renal failure may adversely affect the hypothalamic-pituitary-ovarian axis. Tests of ovarian reserve include follicle-stimulating hormone (FSH), antral follicle count, and anti-Müllerian hormone level.

Prevention of medication-induced infertility is important. Concurrent treatment with a long-acting GnRH analogue (e.g., leuprolide) may decrease risk of premature ovarian failure in CYC-treated patients, although long-term data are limited.[124] Embryo and oocyte cryopreservation are good options to preserve fertility in patients who are stable enough to undergo ovarian hyperstimulation but are not able or ready to pursue pregnancy.

Common assisted reproduction techniques include ovarian induction (OI), with or without IVF, and embryo

**TABLE 39-4** Benefits and Risks of Contraceptive Methods for Rheumatic Disease Patients

| | Copper IUD | LNG IUD | Progestin Pill | DMPA | Progestin Implant | Comb OC | Vaginal Ring | Patch |
|---|---|---|---|---|---|---|---|---|

transfer. IVF cycles require more aggressive hyperstimulation with surgical extraction of oocytes, fertilization, and reimplantation. Although rare, ovarian hyperstimulation syndrome (OHSS) is an important complication that results in capillary leak with pleural effusion and ascites; severe OHSS increases risk for thrombosis and renal compromise, particular issues of concern for rheumatology disease patients. Important risks for rheumatic disease patients relate to the elevated estrogen levels and include lupus flare and thrombosis.[125,126] SLE patients with OI/IVF–induced flare generally have good outcomes. Thrombosis in aPL-positive or APS patients undergoing OI/IVF appears to be rare, although most reported patients have been treated prophylactically with aspirin or LMWH. Data do not support aPL as a cause of failed IVF or infertility, and so anticoagulation is not indicated to improve IVF cycle outcome.[30] Pre-IVF assessment should mimic the pre-pregnancy evaluation for rheumatic disease patients. OI/IVF should be planned for patients with stable inactive disease on medications compatible with pregnancy. Prophylactic anticoagulation should be considered in patients with high-risk aPL profiles, and is mandatory for confirmed APS patients.

## CONCLUSION

Caring for women with rheumatic disease throughout their reproductive lifespans is both challenging and rewarding. All reproductive-aged rheumatic disease patients on potentially teratogenic medications need to be counseled about effective contraceptive methods. In patients who are treated with cyclophosphamide it is important to discuss fertility-sparing approaches before the initiation of therapy. Common principles of reproductive care for rheumatic disease patients, regardless of specific diagnosis, include identifying the limited number of patients with severe disease-related damage who should avoid pregnancy, counseling patients to conceive when disease has been stable and inactive on medications considered low risk for pregnancy, and assessing particular risk factors for outcome such as anti-phospholipid and anti-Ro/SS-A and anti-La/SS-B antibodies. Finally, a plan for medication use in the case of disease flare during pregnancy should be agreed upon by the patient and treating clinician at the onset of pregnancy. With careful planning, most women with rheumatic disorders can anticipate a successful pregnancy with a good outcome.

CHAPTER 40

# History and Physical Examination of the Musculoskeletal System

John M. Davis III • Kevin G. Moder • Gene G. Hunder

**KEY POINTS**

- A detailed and accurate history is crucial to make the correct diagnosis in patients with musculoskeletal diseases.
- The primary symptoms of musculoskeletal disease are pain, joint stiffness, swelling, limitation of motion, weakness, fatigue, and loss of function.
- An understanding of the anatomy, the planes of motion and, particularly, the configuration of the synovial lining, is imperative for proper physical diagnosis of musculoskeletal diseases.
- It is important to record qualitative and quantitative aspects of the joint examination to monitor disease activity in patients with inflammatory arthropathies.
- Early recognition of how patients' psychosocial factors affect their musculoskeletal symptoms and musculoskeletal examination enhances clinical assessment.

## HISTORY IN A PATIENT WITH MUSCULOSKELETAL DISEASE

An accurate and comprehensive history of a patient's musculoskeletal symptoms is crucial to make the correct diagnosis. This history must include a precise understanding of what the patient means by his or her description of symptoms. The physician must obtain a detailed account of symptom onset, location, patterns of progression, and severity, as well as exacerbating and alleviating factors and associated symptoms. The relationship of the symptoms to psychosocial stressors is important and should be determined. The impact of the symptoms on all aspects of the patient's functioning must be assessed to guide therapy.

The effects of current or previous therapy on the course of the illness are helpful in efforts to understand current symptoms. Response to anti-inflammatory or glucocorticoid medications may suggest an inflammatory origin. Such responses are not specific to inflammatory rheumatic diseases, however, and must be considered in light of the entire history and physical examination. The physician must assess compliance with therapies for musculoskeletal diseases. Noncompliance with the recommended treatment must be differentiated from treatment failure as the explanation for the patient's lack of improvement.

While the physician is taking the patient's history, the patient provides verbal and nonverbal clues to the nature of the illness and how the patient has responded to it. Patients with early rheumatoid arthritis (RA) may hold their hands in a flexed posture to minimize intra-articular pressure and pain. Some patients may be overly concerned, whereas others may seem inappropriately indifferent to their symptoms. The physician must appreciate the patient's understanding of the illness and attitudes toward it to begin effective treatment.

### Pain

Pain is the most common symptom that brings a patient with musculoskeletal diseases to the physician. Pain is a subjective hurting sensation or experience that is described in various terms, often of actual or perceived physical damage. Pain is a complex sensation that is difficult to define, qualify, and measure. The patient's pain may be modified by emotional factors and previous experiences.

The character of the pain usually is best defined early in the interview because this can be helpful in categorizing the patient's complaints. Aching in a joint area suggests an arthritic disorder, whereas burning or numbness in an extremity may indicate a neuropathy. Descriptions of pain as "excruciating" or "intolerable" when the patient is otherwise able to function provide a clue that emotional or psychosocial factors are contributing to or amplifying the symptoms.

The physician must elicit the distribution of the patient's pain and determine whether this fits with anatomic structures. Patients describe their pain location in terms of body part names, but frequently the terms are used in a nonanatomic manner. Patients frequently complain of "hip" pain when they are actually referring to pain in the low back, buttock, or thigh. The interviewer must attempt to clarify this complaint by asking the patient to point to the area of pain with one finger. Pain localized in the distribution of a joint or joints likely reflects an articular disorder. Pain may localize to bursae, tendons, ligaments, or nerves, implying disorders of these structures. In contrast to superficial structures, deep structures often give rise to poorly localizing pain. Similarly, pain arising from small, peripheral joints is often more focal than pain arising from proximal, large joints, such as the shoulders and hips. Pain

that is widespread, is vaguely described, and does not respect anatomic distributions generally suggests a chronic pain syndrome, such as fibromyalgia or psychiatric disease.

The severity of the pain should be assessed. A common approach is to ask the patient to describe the level of pain on a numeric scale of intensity from 0 (no pain) to 10 (very severe pain). To monitor disease activity of inflammatory arthritis, measuring pain on a visual analogue scale by having the patient mark the severity of pain during the past week on a 100-mm line can be helpful. Similar scales are used in validated instruments, such as the McGill Pain Questionnaire.

The physician must determine what exacerbates and alleviates the pain. Joint pain present at rest but worse with movement suggests an inflammatory process, whereas pain that occurs primarily with activity and is relieved by rest usually indicates a mechanical disorder such as degenerative arthritis. Timing of pain symptoms during the day and night also provides important information, as discussed in the next section.

## Stiffness

Stiffness is a common complaint among patients with arthritis. What is meant by stiffness varies from patient to patient, however. Some patients may use the term *stiffness* to refer to pain, soreness, weakness, fatigue, or limitation of motion.[1] Rheumatologists generally use the term *stiffness* to describe discomfort and limitation when the patient attempts to move the joints after a period of inactivity. This "gel" phenomenon occurs usually after an hour or more of inactivity. The duration of stiffness related to inactivity varies, with mild stiffness lasting minutes and severe stiffness lasting hours.

Morning stiffness is an early feature of inflammatory arthropathies and is particularly noted in RA and polymyalgia rheumatica, in which morning stiffness may last for several hours. The absence of morning stiffness does not exclude inflammatory arthritis, but its absence is uncommon. A useful question to assess morning stiffness is this: "In the morning, how long does it take for your joints to limber up to as good as they are going to get for the day?" Morning stiffness associated with non-inflammatory joint diseases, such as degenerative arthritis, generally is of short duration (usually <30 minutes) and is less severe than stiffness of inflammatory joint disease. Additionally, the degree of stiffness in non-inflammatory joint diseases is related to the extent of use of the damaged joint: stiffness is worse after excessive use, generally improving within several days to the baseline level. Morning stiffness is not specific for inflammatory arthropathies and may be described by patients with fibromyalgia or chronic idiopathic pain syndromes, neurologic disorders, such as Parkinson's disease (although generally without limbering up), and sleep-related breathing disorders.

## Limitation of Motion

Limitation of motion is a common complaint among patients with articular disorders. This complaint must be differentiated from stiffness, which usually is transient and variable, whereas limitation of motion secondary to joint disease is generally fixed and varies less with time. The interviewer should determine the extent of disability resulting from the restriction in joint motion. The duration of the restriction in joint motion frequently predicts the likelihood of improvement with interventions such as oral and intra-articular glucocorticoids or physical therapy. Determining the rapidity of onset of the limitation of motion may be helpful in the differential diagnosis; abrupt onset of the limitation of motion suggests a structural derangement, such as a tendon rupture or torn knee cartilage, whereas insidious onset of restricted joint motion is more common with inflammatory joint disease.

## Swelling

Joint swelling is an important symptom in patients with rheumatic diseases. The presence of true joint swelling narrows the differential diagnosis in a patient with arthralgia. To determine whether the swelling is related to joint synovitis as opposed to soft tissue conditions, clarifying the anatomic location and distribution of the swelling is key. Diffuse soft tissue swelling can occur because of venous or lymphatic obstruction, soft tissue injury, or obesity. The description of swelling in patients with such conditions usually is ill defined or is not in a distribution of particular joints, bursae, or tendons. Obese patients may interpret normal adipose tissue over the medial aspect of the elbow, the knee, or the lateral aspect of the ankle as joint swelling. In contrast, patients with inflammatory arthritis may describe swelling of joints in a distribution typical of a specific disease—symmetric swelling of the metacarpophalangeal joints and wrists in RA, or swelling of several toes and a knee in psoriatic arthritis.

It is useful to delineate the onset and progression of swelling and the factors that influence it. Swelling of a joint resulting from synovitis or bursitis frequently is associated with discomfort with motion because of tension on the inflamed tissues. If swollen tissues are periarticular, however, no discomfort may be present with joint motion because the inflamed tissues are not stressed. Swelling of a confined structure, such as a synovial cavity or bursa, is most painful when it has developed acutely, whereas a similar degree of swelling that has developed slowly often is much more tolerable.

# WEAKNESS

Weakness is another common complaint that can be associated with myriad different subjective meanings. True weakness is the loss of muscle power. When present, it is demonstrable on physical examination.

The temporal course of weakness is important to the differential diagnosis. Weakness of sudden onset without trauma often indicates a neurologic disorder, such as an acute cerebrovascular event, which generally results in a fixed, nonprogressive deficit. Weakness of insidious onset more often suggests a muscle disease, such as an inflammatory myopathy (e.g., polymyositis). The latter tends to be ongoing and progressive. Weakness that is intermittent suggests a disorder of the neuromuscular junction, such as myasthenia gravis. Patients with this disease may describe muscle fatigue with activity as opposed to true weakness.

The physician should determine the distribution of the patient's weakness. Proximal weakness that is bilateral and symmetric suggests an inflammatory myopathy. In contrast, inclusion body myositis causes an asymmetric and more distal weakness. The presence of a unilateral or isolated deficit generally indicates a neurogenic origin. Distal weakness, in the absence of joint findings, generally indicates neurologic disorders, such as peripheral neuropathy. Patients with peripheral neuropathies also complain of pain and sensory symptoms, such as paresthesias. In contrast, patients with inflammatory myopathy often present with painless weakness.

Inquiring about the patient's family history may provide valuable information. A history of other family members with similar symptoms may increase the likelihood that the patient has a hereditary disorder, such as muscular dystrophy or familial neuropathy.

It also is important to review medication taken recently or currently. Many medications, including corticosteroids and lipid-lowering agents, can cause muscle injury. Less commonly, environmental exposure can lead to symptoms of weakness. Heavy metal poisoning causes a peripheral neuropathy. Dietary exposure also should be investigated, such as eating undercooked pork as a source of trichinosis. Excessive alcohol intake has been associated with neuropathy and myopathy.

Taking a complete review of systems is helpful in evaluating a patient with weakness. Constitutional symptoms, such as weight loss and night sweats, may indicate the presence of a malignancy as the cause of generalized weakness. Rash, arthralgia, or Raynaud's phenomenon may prompt further testing for a connective tissue disease.

### Fatigue

Patients with musculoskeletal disorders frequently complain of fatigue. *Fatigue* can be defined as an inclination to rest even though pain and weakness are not limiting factors. Fatigue after varying degrees of activity that is relieved by rest is normal. Patients with rheumatic diseases experience fatigue even without activity. Fatigue generally improves as the systemic rheumatic disease improves. Malaise frequently occurs with, but is not synonymous with, fatigue. Malaise indicates the lack of well-being that often occurs at the onset of an illness. Fatigue and malaise may occur in the absence of identifiable disease, and psychosocial factors, anxiety, or depression may account for the symptoms.

### Loss of Function

The comprehensive history should include an assessment of the patient's ability to perform activities of daily living, as loss of function is a common manifestation of musculoskeletal disease with serious impact on health and quality of life. The extent of disability may vary from loss of the ability to use one finger joint because of arthritis to complete physical incapacitation resulting from severe inflammatory polyarthritis. Irrespective of the cause, loss of physical function often has a profound impact on patient social activities, exercise routine, work capacity, and even basic self-care. Assessing for the presence and degree of functional disability is important to evaluate the severity of illness and in making treatment recommendations, particularly in RA, in which disability is among the strongest predictors of long-term outcomes and mortality.[2-4]

Functional capacity is assessed first by asking general questions about the patient's ability to perform daily activities, including grooming, dressing, bathing, eating, walking, climbing stairs, opening doors, carrying objects, and so forth. A report of a specific loss of function, such as difficulty opening a milk carton, should be investigated further to clarify why the task is difficult, which will inform the differential diagnosis and guide clinical examination. This information will also yield important information for management, such as opportunities for physical and occupational therapy, use of splints/braces, and so forth. Overall functional capacity may be evaluated with the use of an instrument such as the Health Assessment Questionnaire (see Chapter 33), which is widely used in research and in the clinic to monitor changes in physical function in response to therapy among patients with RA and other rheumatic diseases.

## SYSTEMATIC METHOD OF EXAMINATION

The musculoskeletal examination should be a systematic, thorough assessment of the status of the joints, periarticular soft tissues, tendons, ligaments, bursae, and muscles. Rheumatologists commonly begin by examining the upper extremities followed by the trunk and lower extremities, but many routines may be effective, provided that a systematic, consistent approach is used. Gentle handling of tender and painful joints enhances cooperation by the patient and allows an accurate evaluation of the joints.

The general aim of the examination of the joints is to detect abnormalities in structure and function. Key signs of articular disease include swelling, tenderness, limitation of motion, crepitus, deformity, and instability.

### General Observation

A general examination of the patient should be performed to look for any signs of systemic illness. This should include an examination of the skin, noting signs of pallor (which may suggest anemia), nodules (which may suggest RA or gout), or rashes (which may suggest lupus, vasculitis, or dermatomyositis). The patient should be appropriately undressed for examination. The physician should assess gait by asking the patient to walk in the examining room or down the hallway, because an antalgic gait may be seen in various musculoskeletal disorders of the spine or lower extremities, and various gait disorders may occur in neuromuscular diseases. The ability of the patient to arise and transfer to the examining table should also be evaluated, as this will provide information on pain, proximal muscle strength, and overall physical function. The patient should be assessed for appearance of the muscles, including bulk, tone, and tenderness. Muscle bulk should be compared on one side of the body with the other to look for any asymmetry, hypertrophy, or atrophy. The patient's manner and body language may provide information on his or her mood and anxiety level, which merits consideration in evaluating pain and tenderness.

## Swelling

Swelling around a joint may be caused by intra-articular effusion, synovial proliferation, periarticular subcutaneous tissue inflammation, bursitis, tendinitis, bony enlargement, or extra-articular fat pads. A keen understanding of the anatomic configuration of each joint's synovial membrane is crucial in differentiating soft tissue swelling secondary to a joint effusion from swelling of periarticular tissues. First, the examiner should inspect the joints for visible evidence of swelling, such as loss of normal landmarks or contours. It is frequently helpful to visually compare the same joints on both sides of the body to detect subtle evidence of swelling and to appreciate symmetry.

Second, the examiner should palpate each joint. The normal synovial membrane is too thin to palpate, whereas the thickened synovial membrane in many chronic inflammatory arthritides, such as RA, may have a "doughy" or "boggy" consistency. In some joints, such as the knee, the extent of the synovial cavity can be delineated on physical examination by compressing the fluid into one of the extreme synovial recesses. The edge of the resulting bulge may be palpated more easily. If this palpable edge is within the anatomic confines of the synovial membrane and disappears on release of compression, the distention usually represents synovial effusion; if it persists, it is an indication of a thickened synovial membrane. Reliable differentiation between synovial membrane thickening and effusion is not always possible by physical examination, however. Ultrasonography is used increasingly as an extension of the physical examination, allowing the examiner to differentiate between synovial proliferation and effusion.

## Tenderness

In the musculoskeletal examination, tenderness is unusual discomfort when the physician palpates and puts pressure on articular and periarticular tissues. Localizing the tenderness to palpation may assist the examiner in determining whether the pathology is intra-articular or periarticular in location, such as a fat pad, tendon attachment, ligament, bursa, muscle, or skin. It can be useful to palpate structures that are not involved to assess the importance of tenderness. Finding tender joints in a patient who also has numerous other myofascial tender points is less of a concern for arthritis than finding tender joints in a patient with no extra-articular tenderness.

## Limitation of Motion

Limitation of motion is a common manifestation of articular disease; the examiner must know the normal type and range of motion for each joint. Comparison of the affected joint with an unaffected joint of the opposite extremity is useful to evaluate individual variation. Restricted joint motion may be caused by changes in the joint itself or in periarticular structures. To distinguish these possibilities, it is crucial to compare the passive with the active range of motion. If the passive range of motion is greater than the active range of motion, the restriction may be the result of pain, weakness, or the state of articular or periarticular structures. It also is important to distinguish muscle tension from a true limitation of joint motion, emphasizing the importance of ensuring relaxation of the patient. Pain that occurs with attempts to move a joint passively to the limit of range of motion in one plane is referred to as *stress pain*. Pain in the joint with attempted active or passive range of motion usually indicates an abnormality in the joint.

## Crepitus

Crepitus is a palpable or audible grating or crunching sensation produced by motion. This sensation may or may not be accompanied by discomfort. Crepitus occurs when roughened articular or extra-articular surfaces are rubbed together by active motion or by manual compression. Fine crepitus often is palpable over joints involved by chronic inflammatory arthritis and usually indicates roughening of the opposing cartilage surfaces as a result of erosion or the presence of granulation tissue. Coarse crepitus may be caused by inflammatory or non-inflammatory arthritis. Bone-on-bone crepitus produces a higher-frequency, palpable, audible squeak. Crepitus from within a joint should be differentiated from cracking or popping sounds caused by the slipping of ligaments or tendons over bony surfaces during motion. The latter phenomena are usually less contributory to the diagnosis of joint disease and may be heard over normal joints. In scleroderma, a distinct, coarse, creaking, leathery crepitus may be palpable or audible over tendon sheaths.

## Deformity

Deformity of the joints may manifest as a bony enlargement, articular subluxation, contracture, or ankylosis in nonanatomic positions. Deformed joints usually do not function normally, frequently restrict activities, and may be associated with pain, especially with overuse. Occasionally, a deformed joint may function well but is a cosmetic concern. Joint deformities may be reversible or irreversible. Multiple swan neck deformities of the fingers that can be corrected with manipulation may indicate Jaccoud's arthropathy of lupus. In contrast, hand deformities in RA generally are not correctable.

## Instability

Joint instability is present when the joint has greater than normal movement in any plane. *Subluxation* refers to a joint in which there is partial displacement of the articular surfaces but still some joint surface-to-surface contact. A dislocated joint has lost all cartilage surface-to-surface contact. Instability is best determined by supporting the joint between the examiner's hands and stressing the adjacent bones in directions in which the normal joint does not move. The patient must be relaxed during the examination because muscle tension may stabilize an otherwise unstable joint. A knee with a deficient ligament might appear stable if the patient contracts the quadriceps muscles during evaluation.

## Other Aspects of the Examination

Examinations of the cervical spine and low back are discussed in Chapters 45 and 47.

## RECORDING THE JOINT EXAMINATION

Documentation of the joint examination is important in making decisions about therapy, monitoring the activity of arthritis, and determining the efficacy of interventions. Many different recording methods have been described. Abbreviations for each joint can be used, such as *PIP* for the proximal interphalangeal joints. The S-T-L system has been used historically to record the degree of swelling (S), tenderness (T), and limitation of motion (L) of each joint on the basis of a quantitative estimate of gradation.[5] This method remains useful but is used less commonly today because of increasing reliance on electronic medical records. It is easier to describe joint findings in narrative form, for example, "there is 2+ swelling of the second and third metacarpophalangeal (MCP) joints," where grade 0 indicates no swelling, grade 1 indicates palpable synovial thickening, grade 2 indicates loss of normal joint contours, and grade 3 indicates frank cystic swelling of the metacarpophalangeal joint. An alternative method is to record joint examination findings by using a schematic skeleton or homunculus. When accuracy is necessary, the range of motion of individual joints may be measured by using a goniometer.

Joint counts are standard assessments to monitor the activity of inflammatory arthritides in practice and in clinical trials.[6] For monitoring disease activity of RA, a 28-joint count for tenderness and swelling has been recommended. To assess the tender joint count, the examiner documents which joints the patient indicates are painful on palpation with enough pressure to blanch the nail bed of the examiner's thumb and index fingers. To assess the swollen joint count, the examiner documents which joints have palpable soft tissue swelling or fluctuance, excluding joints affected only by deformity or bony hypertrophy. The 28-joint count[7] includes the shoulders, elbows, wrists, first to fifth MCP joints, first to fifth proximal interphalangeal joints, and knees on both sides of the body. Compared with more extensive joint counts, the 28-joint count has the advantage of being quick and easy to perform; however, it is limited by the fact that the ankles and metatarsophalangeal joints are not included, so active disease in the feet may be underestimated. The 28-joint count is used to calculate the Disease Activity Score 28 (DAS28),[8] which is a validated instrument used to monitor disease activity.

The function of the joints in normal use is not captured by assessments of tenderness, swelling, or range of motion, so other examination techniques are necessary. Other tests are available that attempt to measure joint function by assessing the patient's ability to perform a coordinated task (e.g., shoulder arc of motion, measuring the 50-foot walk time). The results of such functional tests may vary, however. Biologic factors, such as circadian changes in joint size and grip strength among rheumatoid patients observed during a 24-hour interval, contribute to variability.

## INTERPRETING THE JOINT EXAMINATION

The physician must understand the significance of specific joint findings, both their presence and absence, to make appropriate treatment decisions. As with any diagnostic assessment, the accuracy and reliability of the joint examination are important considerations. With regard to accuracy in detecting physical signs of inflammatory synovitis, numerous studies have shown that joint examination is far less sensitive in detecting synovitis or effusions than high-resolution ultrasonography or magnetic resonance imaging (MRI).[9-11] Although it is true that swollen joints are more specific for active synovitis, recent clinical studies have suggested that joint tenderness has similar value compared with swelling in predicting the progression of radiographic joint damage.[12] Demonstrable physical signs of arthritis may be particularly subtle for patients with early disease.[13] Considering that MRI bone marrow edema is a predictor of radiographic damage, it is notable that one study reported that 35% to 57% of joints with bone marrow edema were negative for physical signs of synovitis.[14] Thus the examiner must consider the physical findings in view of the complete history of joint symptoms to make an accurate diagnosis, assess prognosis, and prescribe management. Ultrasound examination can also be useful in clarifying the interpretation of joint pathology and enhancing confidence in clinical decisions about therapies.[15]

The joint examination is also affected by variability. For observations such as joint tenderness or grip strength, interobserver variability usually is greater than intraobserver variability. Considerable intraobserver variability may be noted in observations of the same patient, even during a short interval. Interobserver reliability, in general, is higher for joint-line tenderness than for swelling and is specifically related to the underlying disease, such as higher reliability of the examination for joint swelling in RA than in psoriatic arthritis.[11]

## EXAMINATION OF SPECIFIC JOINTS

### Temporomandibular Joint

The temporomandibular joint is formed by the condyle of the mandible and the fossa of the temporal bone just anterior to the external auditory canal. It is difficult to visualize swelling of this joint. The examiner may palpate the joint by placing a finger just anterior to the external auditory canal and asking the patient to open and close the mouth and to move the mandible from side to side.[16] The presence of synovial thickness or swelling of minimal or moderate degree can be detected most easily if the synovitis is unilateral or asymmetric compared with the other side. To assess vertical movement of the temporomandibular joint, the examiner should ask the patient to open the mouth maximally and then measure the distance between the upper and lower incisor teeth, normally 3 to 6 cm. Lateral movement can be determined by using incisor teeth as landmarks. Audible or palpable crepitus or clicking may be present in patients with and without evidence of severe arthritis.

Many arthritides can affect the temporomandibular joints, including juvenile and adult RA. Micrognathia may develop in children in whom these joints are affected, as a result of arrested bone growth of the mandible. Arthralgias of the temporomandibular joint may develop in patients without inflammatory arthritis, consistent with the temporomandibular joint syndrome (see Chapter 51). This syndrome is thought by some investigators to result from bruxism and is likely to be a form of myofascial pain, similar to fibromyalgia.

## Cricoarytenoid Joints

The paired cricoarytenoid joints are formed by the articulation of the base of the small pyramidal arytenoid cartilage and the upper posterolateral border of the cricoid cartilage. The vocal ligaments (true vocal cords) are attached to the arytenoid cartilages. The cricoarytenoid joints are diarthrodial joints that normally move medially and laterally and rotate during opening and closing of the vocal cords. Examination of these joints is performed by direct or indirect laryngoscopy. Erythema, swelling, and lack of mobility during phonation may result from inflammation of the joints. The cricoarytenoid joints may be involved in RA, trauma, and infection. Involvement in RA is more common than is clinically apparent. Symptoms may include hoarseness or a sense of fullness or discomfort in the throat, which is worse on speaking or swallowing. Severe airway obstruction may occur in rare cases.

## Sternoclavicular, Manubriosternal, and Sternocostal Joints

The medial ends of the clavicles articulate on each side of the sternum at its upper end to form the sternoclavicular joints. The articulations of the first ribs and the sternum (sternocostal joints) are immediately caudal. The articulation of the manubrium and the body of the sternum is at the level of attachment of the second costal cartilage to the sternum. The third through seventh sternocostal joints articulate distally along the lateral borders of the sternum. The sternoclavicular joints are the only articulations in this group that are always diarthrodial; the others are amphiarthroses or synchondroses. The sternoclavicular joints are the only true points of articulation of the shoulder girdle with the trunk. These joints are just beneath the skin; synovitis usually is visible and palpable. These joints have only slight movement, which cannot be accurately measured.

The sternoclavicular joints are commonly involved by ankylosing spondylitis, RA, and degenerative arthritis, although this involvement is often subclinical. The sternoclavicular joint may be the site of septic arthritis, especially in injection drug users. These joints should be examined for tenderness, swelling, and bony abnormalities. Tenderness of the manubriosternal or sternocostal joints is much more frequent than actual swelling. Tenderness of these joints without actual swelling has been termed *costochondritis;* if actual swelling is present, *Tietze's syndrome* may be the term used.

## Acromioclavicular Joint

The acromioclavicular joint is formed by the lateral end of the clavicle and the medial margin of the acromion process of the scapula. Arthritis of the acromioclavicular joint is most commonly attributable to trauma leading to degenerative arthritis. Bony enlargement of this joint is typically observed, but soft tissue swelling is not usually visible or palpable. Tenderness or pain with adduction of the arm across the chest indicates pathology of the acromioclavicular joint. Movement of this joint occurs with shoulder motion but is difficult to measure accurately. The acromioclavicular joint may be involved by RA or spondyloarthropathies, although these often are not severe enough to come to clinical attention.

## Shoulder

See Chapter 46 for a detailed description.

## Elbow

The elbow joint is composed of three bony articulations (Figure 40-1). The principal articulation is the humeroulnar joint, which is a hinge joint. The radiohumeral and proximal radioulnar articulations allow rotation of the forearm.

To examine the elbow joint, the examiner places his or her thumb between the patient's lateral epicondyle and the olecranon process in the lateral para olecranon groove and places one or two fingers in the corresponding groove medial to the olecranon. The examiner relaxes and passively moves the elbow through flexion, extension, and rotation. The examiner should examine the skin around the elbow joint carefully, noting abnormalities such as psoriatic plaques, rheumatoid nodules, or tophi. It is useful to palpate the olecranon bursa carefully to exclude the presence of small nodules or tophi. Limitation of motion and crepitus should

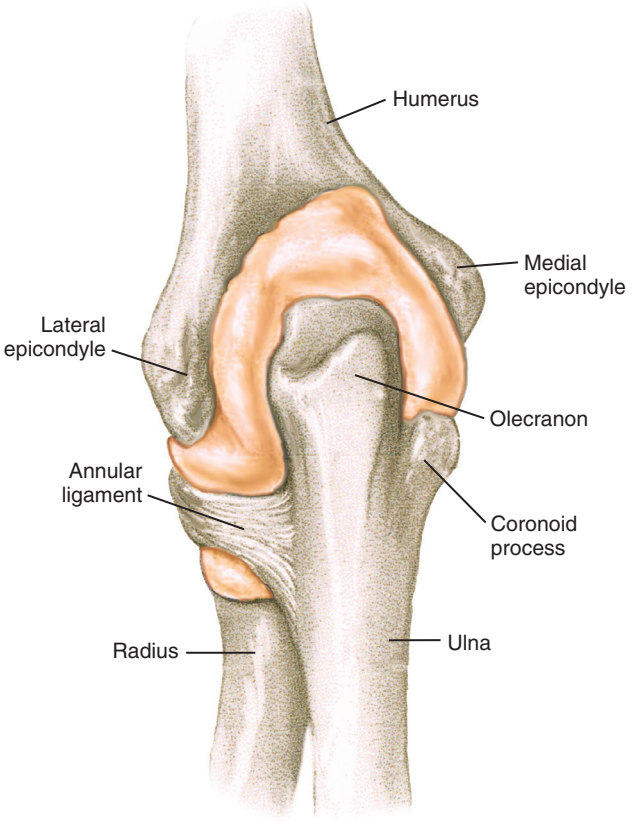

**Figure 40-1** Diagram of the elbow. Posterior aspect of the elbow joint shows radius and ulna in extension and the distribution of the synovial membrane in distention. *(From Polley HF, Hunder GG:* Rheumatologic interviewing and physical examination of the joints*, ed 2, Philadelphia, 1978, WB Saunders. With permission from the Mayo Foundation for Medical Education and Research.)*

be noted. Synovial swelling is most easily palpated because it bulges under the examiner's thumb when the elbow is passively extended. The synovial membrane sometimes can be palpated over the posterior aspect of the joint between the olecranon process and the distal humerus. Synovitis or effusion generally results in limitation of elbow extension.

The olecranon bursa overlies the olecranon process of the ulna. Olecranon bursitis is common after chronic local trauma and in rheumatic diseases, including RA and gout. A septic olecranon bursitis may occur. A patient who has olecranon bursitis usually presents with a swelling over the olecranon process, which is often tender and may be erythematous. Sometimes a large collection of fluid over the area is palpable as a cystic mass, often requiring aspiration and drainage. There is generally no pain with elbow movement.

The medial and lateral epicondyles of the humerus are the sites of attachment of the common flexor and extensor tendons, controlling hand and wrist motion. Tenderness at the epicondyles without swelling or other signs of inflammation may indicate overuse tendinopathy, termed *lateral epicondylitis* (tennis elbow) and *medial epicondylitis* (golfer's elbow). In lateral epicondylitis, discomfort can be elicited by resisted supination of the forearm or resisted extension of the pronated wrist.[17] In medial epicondylitis, discomfort can be elicited by resisted flexion of the supinated wrist.

To assess motor function of the elbow, flexion and extension can be assessed. The principal flexors of the elbow are the biceps brachii (nerve roots C5 and C6), brachialis (C5 and C6), and brachioradialis (C5 and C6) muscles. The principal extensor of the elbow is the triceps brachii muscle (C7 and C8). Occasionally, a patient may rupture the attachment site of one of the heads of the biceps, resulting in visible and palpable muscle swelling on the anterior upper arm.

## Wrist and Carpal Joints

The wrist is a complex joint formed by many articulations between the radius, the ulna, and the carpal bones. The true wrist or radiocarpal articulation is a biaxial ellipsoid joint formed proximally by the distal end of the radius and the triangular fibrocartilage and distally by a row of three carpal bones: scaphoid (navicular), lunate, and triquetrum (triangular). The distal radioulnar joint is a uniaxial pivot joint. The midcarpal joints are formed by the junction of the proximal and distal rows of the carpal bones. The midcarpal and carpometacarpal articular cavities often communicate. The intercarpal joints refer to the articulations between individual carpal bones.

Movements of the wrist include flexion (palmar flexion), extension (dorsiflexion), radial deviation, ulnar deviation, and circumduction. Pronation and supination of the hand and forearm occur primarily at the proximal and distal radioulnar joints. The only carpometacarpal joint that moves to a notable degree is the carpometacarpal joint of the thumb. This joint is saddle-shaped and moves in three planes. Crepitus at this joint is common because it is frequently involved in degenerative arthritis.

The wrist normally can be extended to 70 to 80 degrees and flexed to 80 to 90 degrees. Ulnar and radial deviation should allow 50 degrees (ulnar) and 20 to 30 degrees (radial) of movement. Loss of extension is the most incapacitating functional impairment of wrist motion.

The long flexor tendons of the forearm musculature cross the volar aspect of the wrist and are enclosed in the flexor tendon sheath under the flexor retinaculum (transverse carpal ligament). The flexor retinaculum and the underlying carpal bones form the carpal tunnel. The median nerve passes through the carpal tunnel superficial to the flexor tendons. The extensor tendons of the forearm musculature are enclosed by six synovial lined compartments.

The palmar aponeurosis (fascia) spreads out into the palm from the flexor retinaculum. Dupuytren's contracture, a fibrosing condition, affects the palmar aponeurosis, which becomes thickened and contracted and may draw one or more fingers into flexion at the metacarpophalangeal joint. The fourth finger is frequently affected first.

Swelling of the wrist may be caused by effusion, synovial proliferation, or both, of the tendon sheaths (tenosynovitis), the wrist joint, or a combination thereof. When swelling is attributable to tenosynovitis, swelling is localized to the distribution of a particular tendon sheath or compartment (i.e., ulnar swelling attributable to tenosynovitis of the flexor carpi ulnaris tendon), tends to be more localized, and moves with flexion and extension of the fingers (Figure 40-2). Articular swelling tends to be more diffuse and protrudes anteriorly and posteriorly from under the tendons (Figure 40-3).

Synovitis of the wrist is best detected by palpation of the dorsal aspect of the joint. Accurate localization of the synovial margins is difficult because of structures overlying the volar and dorsal aspects of the wrist. To examine the wrist, the examiner should palpate the joint gently between the thumbs dorsally and the fingers on the volar aspect. Thickening or frank synovial proliferation of the synovium should be noted. When this thickening or proliferation is severe, the range of motion of the wrist joint frequently is limited and associated with stress pain.

A ganglion is a cystic enlargement arising from a joint capsule. Ganglions characteristically occur at the volar or dorsal aspect of the wrist between the tendons.

Subluxation of the ulna may develop as a result of severe chronic inflammatory arthritis. The subluxated ulna appears as a prominence on the dorsomedial wrist. Chronic irritation of the extensor tendons, primarily the fourth and fifth finger extensor tendons, may cause these tendons to rupture.

*Trigger fingers* secondary to stenosing tenosynovitis can be detected by palpating crepitus or nodules along the tendons in the palm while the patient slowly flexes and extends the fingers.[18] The patient usually gives a history of the affected finger catching or locking with movement.

Tenosynovitis of the first extensor compartment, which encloses the abductor pollicis longus and extensor pollicis brevis muscles of the thumb, is known as de Quervain's tenosynovitis. Patients complain of pain at the radial aspect of the wrist. Tenderness may be elicited by palpating near the radial styloid process. The examiner performs the Finkelstein test for de Quervain's tenosynovitis by asking the patient to make a fist with the thumb enclosed in the palm of the hand, then to move the wrist into ulnar deviation. Severe pain over the radial styloid is a positive finding, often indicating stretching of the thumb tendons in a stenosed tendon sheath.

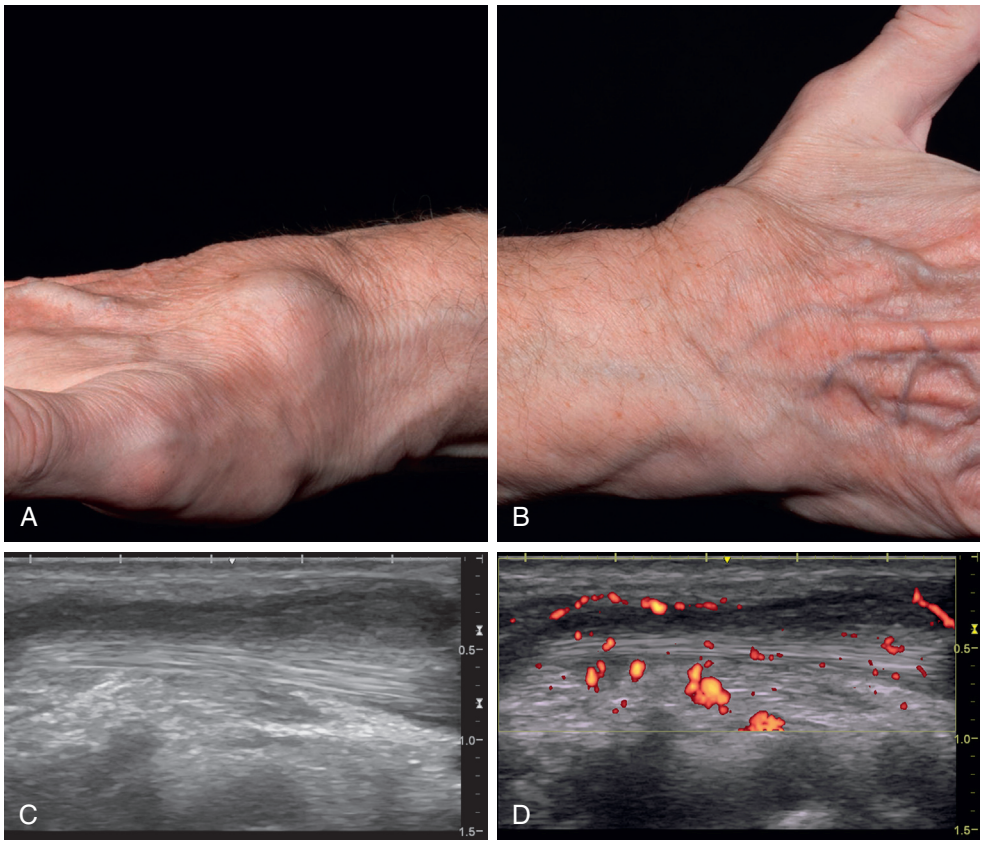

**Figure 40-2** Tenosynovitis of the wrist. **A**, Radial and **B**, dorsal views of the wrist in a patient with rheumatoid arthritis. Note the localized swelling at the dorsoradial aspect of the wrist. Sonographic evaluation of this patient revealed evidence of **C**, hypoechoic thickening of the third dorsal extensor compartment with **D**, hyperemia as detected by power Doppler signal, consistent with active inflammatory tenosynovitis.

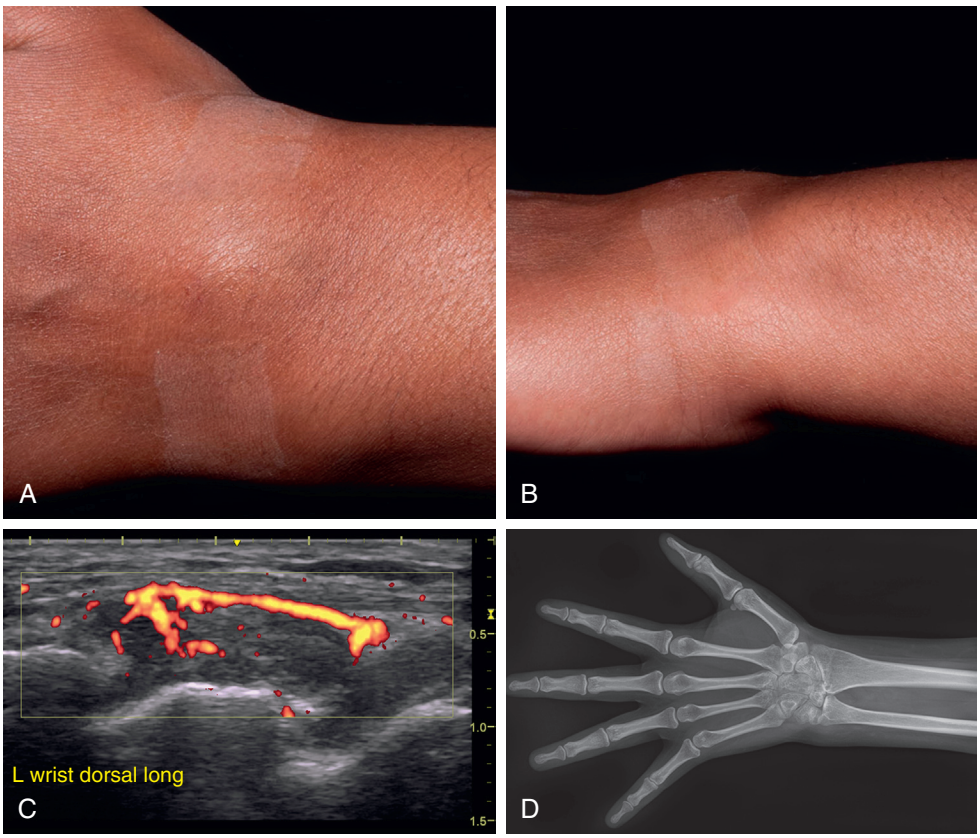

**Figure 40-3** Synovitis of the wrist. **A**, Dorsal and **B,** radial views of the wrist in another patient with rheumatoid arthritis. Note diffuse swelling through the dorsal recess of the wrist. **C**, Sonographic evaluation reveals hypoechoic thickening and power Doppler hyperemia. **D**, Corresponding plain radiograph of the wrist demonstrates carpal erosions and joint space narrowing.

Carpal tunnel syndrome results from pressure on the median nerve in the carpal tunnel. Carpal tunnel syndrome is discussed in detail in Chapter 50.

Muscle function of the wrist may be measured by testing flexion and extension and supination and pronation of the forearm. The principal flexors of the wrist are the flexor carpi radialis (nerve roots C6 and C7) and flexor carpi ulnaris (C8 and T1) muscles. Each of these muscles can be tested separately. This testing can be accomplished if the examiner provides resistance to flexion at the base of the second metacarpal bone in the direction of extension and ulnar deviation in the case of the flexor carpi radialis muscle and resistance at the base of the fifth metacarpal in the direction of extension and radial deviation in the case of the flexor carpi ulnaris muscle. The principal extensors of the wrist are the extensor carpi radialis longus (C6 and C7), extensor carpi radialis brevis (C6 and C7), and extensor carpi ulnaris (C7 and C8) muscles. The radial and ulnar extensor muscles can be tested separately. The principal supinators of the forearm are the biceps brachii (C5 and C6) and supinator (C6) muscles. The principal pronators of the forearm are the pronator teres (C6 and C7) and pronator quadratus (C8 and T1) muscles.

## Metacarpophalangeal and Proximal and Distal Interphalangeal Joints

The metacarpophalangeal joints are hinge joints. Lateral collateral ligaments that are loose in extension tighten in flexion, preventing lateral movement of the digits. The extensor tendons that cross the dorsum of each joint strengthen the articular capsule. When the extensor tendon of the digit reaches the distal end of the metacarpal head, it is joined by fibers of the interossei and lumbricales muscles and expands over the entire dorsum of the metacarpophalangeal joint and onto the dorsum of the adjacent phalanx. This expansion of the extensor mechanism is known as the *extensor hood*.

The proximal and distal interphalangeal joints also are hinge joints. The ligaments of the interphalangeal joints resemble those of the metacarpophalangeal joints. When the fingers are flexed, the bases of the proximal phalanges slide toward the palmar side of the heads of the metacarpal bones. The metacarpal heads form the rounded prominences of the knuckles, with the metacarpal joint spaces situated about 1 cm distal to the apex of the prominences.

To examine the metacarpophalangeal joints, the examiner should palpate the dorsal and volar aspects of each joint in 20 to 30 degrees of flexion (Figure 40-4). The skin on the palmar surface of the hand is thick and covers a fat pad between it and the metacarpophalangeal joint. This makes palpation of the palmar surface of the joint difficult. It is especially helpful in examining the small joints to compare one with another to detect subtle synovitis. Gentle lateral compression with force applied at the base of the second and fifth metacarpophalangeal joints (the *squeeze test*) often elicits pain if synovitis is present.

The proximal and distal interphalangeal joints are best examined by palpating gently over the lateral and medial aspects of the joint, where the flexor and extensor tendons do not interfere with assessment of the synovial membrane. Alternatively, the joint can be compressed anteroposteriorly by the thumb and index finger of one of the examiner's hands, while the other thumb and index finger palpate for synovial distention medially and laterally. The Bunnell test is useful in differentiating synovitis of the proximal interphalangeal joints from tightening of the intrinsic muscles (see Chapter 50).

**Figure 40-4** Palpation of the metacarpophalangeal joints is done with the examiner's thumbs palpating the dorsal aspect of the patient's joint, while the forefingers palpate the volar aspect of the metacarpal head. The joints should be examined while the examiner holds the patient's hand in a relaxed position of partial flexion.

Swelling of the fingers may result from articular or periarticular causes. Synovial swelling usually produces symmetric enlargement of the joint itself, whereas extra-articular swelling may be diffuse and may extend beyond the joint space. Asymmetric enlargement, involving only one side of the digit or joint, is less common and usually indicates an extraarticular process. Diffuse swelling of an entire digit, known by the terms *dactylitis* and *sausage digit*, may result from tenosynovitis and is seen most commonly in the spondyloarthropathies, such as reactive arthritis or psoriatic arthritis. Rheumatoid nodules are firm periarticular swellings that frequently overlie the joints or bony prominences in patients with chronic rheumatoid disease. Chronic swelling with distention of the metacarpophalangeal joints tends to produce stretching and laxity of the articular capsule and ligaments. This laxity, combined with muscle imbalance and other forces, eventually results in the extensor tendons of the digits slipping off the metacarpal heads to the ulnar sides of the joints. The abnormal pull of the displaced tendons is one of the factors that cause ulnar deviation of the fingers in chronic inflammatory arthritis (Figure 40-5).

Swan neck deformity describes a finger with a flexion contracture of the metacarpophalangeal joint, hyperextension of the proximal interphalangeal joint, and flexion of the distal interphalangeal joint. These changes are produced by contraction of the interossei and other muscles that flex the metacarpophalangeal joints and extend the proximal interphalangeal joints. This deformity is characteristic of RA but may be seen in other chronic arthritides (Figure 40-6).

Boutonnière deformity describes a finger with a flexion contracture of the proximal interphalangeal joint associated with hyperextension of the distal interphalangeal joint. The

**Figure 40-5** Destructive rheumatoid arthritis. Chronic synovial pannus formation involves the metacarpophalangeal joints of both hands and both wrist joints. Subluxation and ulnar deviation are present in the right hand metacarpophalangeal joints. Swan neck deformities are present in the right third through fifth and left second through fourth digits.

**Figure 40-6** Swan neck deformity in a patient with psoriatic arthritis. Note hyperextension of the proximal interphalangeal joint and hyperflexion of the distal interphalangeal joint of the second digit. Also note the psoriatic changes of the third and fourth fingernails.

deformity is common in RA and occurs when the central slip of the extensor tendon of the proximal interphalangeal joint becomes detached from the base of the middle phalanx, allowing palmar dislocation of the lateral bands. The dislocated bands cross the fulcrum of the joint and act as flexors instead of extensors of the joint.

Another abnormality is telescoping or shortening of the digits produced by resorption of the ends of the phalanges secondary to destructive arthropathy. This may be seen in the arthritis mutilans form of psoriatic arthritis. Shortening of the fingers is associated with wrinkling of the skin over involved joints and is called *opera-glass hand* or *la main en lorgnette*.

A mallet finger results from avulsion or rupture of the extensor tendon at the level of the distal interphalangeal joint. With this deformity, the patient is unable to extend the distal phalanx, which remains in a flexed position. This deformity frequently results from traumatic injuries.

The Murphy sign is a test for lunate dislocation. The patient is asked to make a fist. The third metacarpal head usually is more prominent than the second and fourth. If the third metacarpal is level with the second and fourth, the finding is positive for lunate dislocation.

Involvement of the distal interphalangeal joints in RA is uncommon. Bony hypertrophy and osteophyte formation are commonly seen, however, at the distal and proximal interphalangeal joints in patients with osteoarthritis. Enlarged, bony, hypertrophic distal interphalangeal joints are called *Heberden nodes*, whereas similar changes at the proximal interphalangeal joints are called *Bouchard nodes*. These usually are easily differentiated from the synovitis of inflammatory arthritis because, on palpation, the enlargement is hard or bony. In addition, signs of inflammation are minimal. Heberden and Bouchard nodes should be easily distinguished from rheumatoid nodules, but patients occasionally confuse these when describing swellings over joints. The examiner should be aware of other causes of joint enlargement or nodules on the hands, including tophaceous gout (Figure 40-7) and, rarely, multicentric reticulohistiocytosis. The first carpometacarpal joint also is often affected in osteoarthritis (Figure 40-8).

The patient's fingernails should be inspected for evidence of clubbing or other abnormalities. Often in patients with psoriatic arthritis, ridging, onycholysis, or nail pitting is present. Occasionally, patients with osteoarthritis develop a groove deformity of the nail on a digit with a Heberden node. (This nail deformity has been called a *Heberden node nail*.) The abnormality is believed to occur secondary to synovial cyst encroachment on the nail bed by the evolving osteoarthritis process. With time, the nail may return to normal.

A crude but sometimes useful assessment of hand function can be made by asking the patient to make a fist. An estimate of the patient's ability to form a full fist can be recorded as a percentage fist, with 100% a complete fist. A fist of 75% indicates that the patient can touch the palm with the fingertips. The ability to oppose fingers, especially the thumb, is crucial to hand function because of the necessity to grasp or at least pinch for objects. If the patient is unable to form a full fist, the ability or inability to pinch or oppose fingers can be demonstrated by asking the patient to pick up a small object.

Strength of the hands can be assessed crudely by asking the patient to grip firmly two or more of the examiner's fingers. More accurate measures of grip strength can be made by using a dynamometer or by having the patient squeeze a partially inflated sphygmomanometer (at 20 mm Hg). It sometimes is useful to test the strength of the fingers separately. The prime movers of flexion of the second through fifth MCP joints are the dorsal and palmar interossei muscles (nerve roots C8 and T1). The lumbricales muscles (C6, C7, and C8) flex the metacarpophalangeal joints when the proximal phalangeal joints are extended. The flexors of the proximal interphalangeal joints are the flexor digitorum superficialis muscles (C7, C8, and T1), and the flexor of the distal interphalangeal joints is the flexor digitorum profundus muscle (C7, C8, and T1).

The prime extensors of the MCP and interphalangeal joints of the second through fifth fingers are the extensor

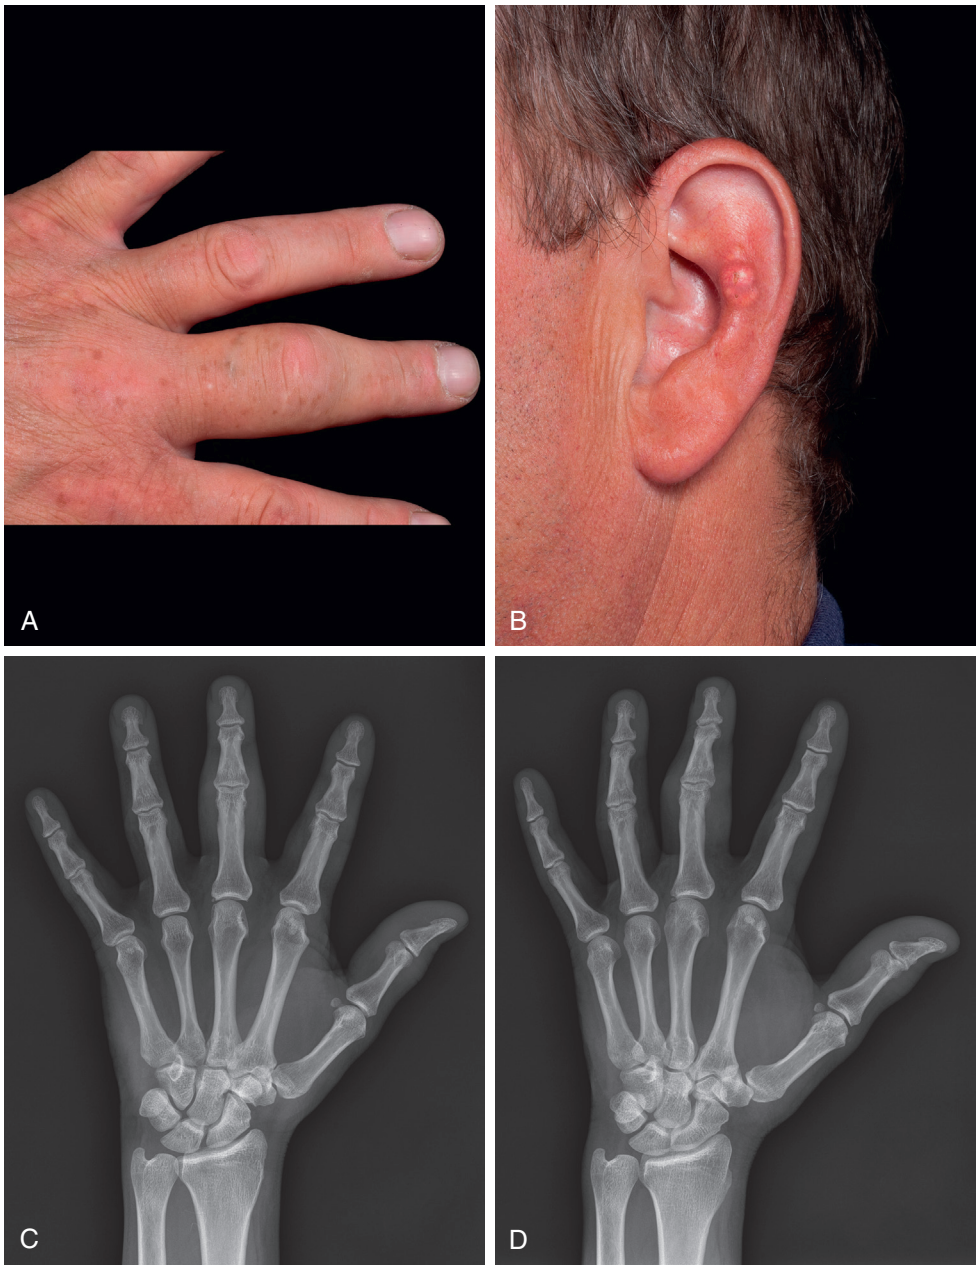

**Figure 40-7** Gout. **A**, Note the swelling and enlargement of the left third proximal interphalangeal joint in a patient with crystal-proven gout. **B**, The same patient was found to have a tophus in the left ear. **C** and **D,** The corresponding posteroanterior and oblique radiographs of the hands demonstrate soft tissue swelling and increased density about the left third proximal interphalangeal joint likely due to tophaceous deposits.

digitorum communis (nerve roots C6, C7, and C8), extensor indicis proprius (C6, C7, and C8), and extensor digiti minimi (C7) muscles. The interossei and lumbricales muscles simultaneously flex the metacarpophalangeal joints and extend the interphalangeal joints. The dorsal interossei (C8 and T1) and abductor digiti minimi (C8) muscles abduct the fingers, whereas the palmar interosseous muscles adduct the fingers.

The thumb is moved by several muscles. The prime flexor of the first metacarpophalangeal joint is the flexor pollicis brevis muscle (nerve roots C6, C7, C8, and T1). The prime flexor of the interphalangeal joint is the flexor pollicis longus muscle (C8 and T1). The metacarpophalangeal joint of the thumb is extended by the extensor pollicis brevis muscle, and the prime extensor of the interphalangeal joint is the extensor pollicis longus muscle (C6, C7, C8, and C9).

The principal abductors of the thumb are the abductor pollicis longus (nerve roots C6 and C7) and the abductor pollicis brevis (C6 and C7) muscles. Motion occurs primarily at the carpometacarpal joint. The principal adductor of the thumb is the adductor pollicis muscle (C8 and T1). Motion occurs primarily at the carpometacarpal joint. The principal movers in opposition of the thumb and fifth fingers are the opponens pollicis (C6 and C7) and opponens digiti minimi (C8 and T1) muscles.

Sensation and nerve injuries in the upper extremity are discussed in Chapters 45 and 50.

**Figure 40-8** Osteoarthritis of the hands. Note the advanced hypertrophic enlargement at the base of both thumbs. Both second distal interphalangeal joints are notable for advanced bony enlargement, and more moderate changes are seen in the other interphalangeal joints.

## Hip

The hip is a spheroidal or ball-and-socket joint formed by the rounded head of the femur and the cup-shaped acetabulum (see Chapter 48). Stability of the joint is ensured by the fibrocartilaginous rim of the glenoid labrum and the dense articular capsule and surrounding ligaments, including the iliofemoral, pubofemoral, and ischiocapsular ligaments that reinforce the capsule. Support also is provided by the powerful muscle groups that surround the hip. The principal hip flexor is the iliopsoas muscle assisted by the sartorius and rectus femoris muscles. Hip adduction is accomplished by the three adductors (longus, brevis, and magnus) plus the gracilis and pectineus muscles. The gluteus medius is the major hip abductor, whereas the gluteus maximus and hamstrings extend the hip. Several clinically important bursae are found around the hip joint. Anteriorly, the iliopsoas bursa lies between the psoas muscle and the joint surface. The trochanteric bursa lies between the gluteus maximus muscle and the posterolateral greater trochanter, and the ischiogluteal bursa overlies the ischial tuberosity.

Examination of the hip should begin by observation of the patient's stance and gait. The patient should stand in front of the examiner so that the anterior iliac spines are visible. Pelvic tilt or obliquity may be present and related to structural scoliosis, anatomic leg-length discrepancy, or hip disease.

Hip contractures may result in abduction or adduction deformities. To compensate for an adduction contracture, the pelvis is tilted upward on the side of the contracture. This allows the legs to be parallel during walking and weight bearing. With a fixed abduction deformity, the pelvis becomes elevated on the normal side during standing or walking. This elevation causes an apparent shortening of the normal leg and forces the patient to stand or walk on the toes of the normal side or to flex the knee on the abnormal leg. Viewed from behind with the legs parallel, the patient with hip disease and an adducted hip contracture may have asymmetric gluteal folds secondary to pelvic tilt, with the diseased side elevated. In this situation, the patient is unable to stand with the foot of the involved leg flat on the floor. In abduction contracture, the findings are reversed; with both legs extended and parallel, the uninvolved side is elevated.

A hip flexion deformity commonly occurs in diseases of the hip. Unilateral flexion of the hip in the standing position reduces weight bearing on the involved side and relaxes the joint capsule, causing less pain. This posture is best noted by observing the patient from the side. A hyperlordotic curve of the lumbar spine compensates for lack of full hip extension.

Gait should be assessed in the patient with possible hip joint disease. With a normal gait, the abductors of the weight-bearing leg contract to hold the pelvis level or to elevate the non–weight-bearing side slightly. Two abnormalities of gait may be commonly observed in patients with hip disease. The most common abnormality seen with a painful hip is the antalgic (limping) gait. With this gait, the individual leans over the diseased hip during the phase of weight bearing on that hip, placing the body weight directly over the joint to avoid painful contraction of the hip abductors. With a Trendelenburg gait, with weight bearing on the affected side, the pelvis drops and the trunk shifts to the normal side. Although the antalgic gait is frequently seen with painful hips, and the Trendelenburg gait is seen in patients with weak hip abductors, these gaits are not specific, and either may occur as a result of hip pain from one of several causes. A mild Trendelenburg gait is seen often in healthy individuals.

The Trendelenburg test assesses the stability of the hip, together with the ability of the hip abductor muscle to stabilize the pelvis on the femur.[19] It is a measure of the gluteus medius hip abductor strength. The patient is asked to stand while bearing weight on only one leg. Normally, the abductors hold the pelvis level or the nonsupported side slightly elevated. If the non–weight-bearing side drops, the test is positive for weakness of the weight-bearing side hip abductors, especially the gluteus medius muscle. This test is nonspecific and may be used in primary neurologic or muscle disorders and in hip diseases that lead to weakness of the hip abductors.

The motion of the hip should be assessed with the patient in the supine position. Range of motion of the hip includes flexion, extension, abduction, adduction, internal and external rotation, and circumduction. The degree of flexion permitted varies with the manner with which it is assessed. When the knee is held flexed at 90 degrees, the hip normally flexes to an angle of 120 degrees between the thigh and the long axis of the body. If the knee is held in extension, the hamstrings limit hip flexion to approximately 90 degrees. The presence of a hip flexion contracture is suggested by the persistence of lumbar lordosis and pelvic tilt, which masks the contracture by allowing the involved leg to remain in contact with the examination table. The Thomas test shows the flexion contracture. With this test, the opposite hip is fully flexed to flatten the lumbar lordosis and fix the pelvis. The patient's involved leg should be extended toward the examination table as far as possible. Flexion contracture of the diseased hip becomes more obvious and can be estimated in degrees from full extension. Measurement for leg-length discrepancy is performed with

the patient in a supine position and the legs fully extended. Each leg is measured from the anterior superior iliac spine to the medial malleolus. A difference of 1 cm or less is unlikely to cause any abnormality of gait and may be considered normal. In addition to true leg-length asymmetries, apparent leg-length discrepancies may result from pelvic tilt or abduction or adduction contractures of the hip.

Abduction is measured with the patient in a supine position and the leg in an extended position, perpendicular to the pelvis. Pelvic stabilization is achieved by the examiner placing an arm across the pelvis with the hand on the opposite anterior iliac spine. With the other hand, the examiner grasps the patient's ankle and abducts the leg until the pelvis begins to move. Abduction to approximately 45 degrees is normal. It is helpful to compare one side with the other because the normal range of motion may vary. Alternatively, the examiner could stand at the foot of the table, grasp both of the patient's ankles, and simultaneously abduct both legs. Abduction is commonly limited in hip joint disease. The examiner assesses adduction by grasping the patient's ankle and raising the leg off the examination table by flexing the hip enough to allow the tested leg to cross over the opposite leg. Normal adduction is approximately 20 to 30 degrees. Hip rotation may be tested with the hip and knee flexed to 90 degrees or with the leg extended. Normal hip external rotation and internal rotation are observed to 45 degrees and 40 degrees, respectively. The difference in rotation between the flexed and extended hip is attributable to increased stabilization of the joint by surrounding ligaments in the extended position. Rotation decreases with extension. To test hip rotation, the examiner grasps the extended leg above the ankle and rotates it externally and internally from the neutral position. Limitation of internal rotation of the hip is a sensitive indicator of hip joint disease.

Extension is tested with the patient in the prone position. Estimating hip extension can be difficult because some of the apparent motion arises from hyperextension of the lumbar spine, pelvis rotation, motion of the buttock soft tissue, and flexion of the opposite hip. The pelvis and the lumbar spine can be partially immobilized by the examiner placing an arm across the posterior iliac crest and the lower lumbar spine. The examiner places the other hand under the thigh with the knee flexed and hyperextends the thigh. Normal extension ranges from 10 to 20 degrees. Limitation of extension often occurs secondary to a hip flexion contracture

Swelling around the hip only rarely can be discerned on examination. The flexion abduction external rotation (FABER) test, also known as the *Patrick* test, is a commonly used screening test for intra-articular hip pathology.[20] To perform this test, the examiner has the patient lie in a supine position with the foot ipsilateral to the test hip, resting on the contralateral knee. The examiner then slowly lowers the patient's test leg toward the examining table, applying gentle pressure to the knee of the test hip and the contralateral anterior superior iliac spine. Normally, the test leg will fall at least parallel to the opposite leg. The FABER test is considered positive when the maneuver reproduces the patient's pain. Although very sensitive for hip joint disease, this test is not specific because a positive test may indicate iliopsoas tightness or sacroiliac joint disease.

The iliotibial band is a part of the fascia lata that extends from the iliac crest, sacrum, and ischium over the greater trochanter to the lateral femoral condyle, tibial condyle, and fibular head, and along the lateral intermuscular system, separating the hamstrings from the vastus lateralis muscle. The tensor fasciae latae muscle may produce an audible snap while it slips over the greater trochanter if the weight-bearing leg moves from hip flexion and adduction to a neutral position, as when climbing stairs. Most commonly observed in young women, the snapping hip usually does not cause severe pain. The Ober test evaluates the iliotibial band for contracture. The patient lies on the side, with the lower leg flexed at the hip and knee. The examiner abducts and extends the upper leg with the knee flexed at 90 degrees. The hips should be slightly extended to allow the iliotibial band to pass over the greater trochanter. The examiner slowly lowers the patient's limb with the muscles relaxed. A positive test result indicative of an iliotibial band contracture occurs if the leg does not fall back to the level of the tabletop.

A common cause of lateral hip pain is trochanteric bursitis. Patients with this condition often complain of pain and tenderness when they attempt to lie on the affected side or climb stairs. The greater trochanter should be palpated for tenderness and compared with the opposite side. In trochanteric bursitis, this area is usually exquisitely tender. The pain of trochanteric bursitis is aggravated by actively resisted abduction of the hip. Aching and tenderness over the buttock area may be secondary to an ischial bursitis. Other causes of lateral and posterior hip (buttock) discomfort include pain at muscle and tendon insertion sites.

Anterior hip and groin pain may be secondary to hip abnormality, most commonly degenerative arthritis. The examiner should take note of decreased range of motion in these patients. Other causes include iliopsoas bursitis, in which swelling and tenderness may be noted in the middle third of the inguinal ligament lateral to the femoral pulse. This pain is aggravated by hip extension and is reduced by flexion. The bursitis may be a localized problem or may represent extension of hip synovitis. It usually is impossible to distinguish between a localized bursitis and an extension of hip synovitis on the basis of the physical examination. If the patient has tenderness in the region of the iliopsoas bursa, but no swelling is palpable, the examiner should consider tendinitis of the iliopsoas muscle. The inguinal region should be palpated for other abnormalities, such as hernias, femoral aneurysms, adenopathy, tumor, and psoas abscess or masses.

Muscle strength testing should include the hip flexors, extensors, abductors, and adductors. The primary hip flexor is the iliopsoas muscle (nerve roots L2 and L3). Flexion may be tested with the patient sitting at the edge of a table. The examiner exerts downward pressure against the thigh proximal to the knee while the patient attempts to flex the hip. The pelvis may be stabilized by the examiner's other hand placed on the ipsilateral iliac crest. Alternatively, with the patient supine and holding the leg in 90 degrees of flexion at the hip, the examiner may attempt to straighten the hip.

Hip extension is tested with the patient lying prone. The primary hip extensor is the gluteus maximus muscle (L5 and S1). With the patient's knee flexed to remove hamstring action, the patient is instructed to extend the hip and thigh

off the surface of the table while the examiner places a forearm across the posterior iliac crest to stabilize the pelvis and applies downward pressure to prevent the lateral trunk muscles from elevating the pelvis and leg off the table.

Abduction may be tested with the patient prone or supine. The patient should abduct the thigh and leg against resistance from the examiner applied at the midthigh level.

The primary adductor is the adductor longus muscle (nerve roots L3 and L4). The examiner holds the upper leg proximal to the knee in slight abduction, while the patient resists and attempts to adduct the leg. Testing for abduction and adduction also may be done in the two legs simultaneously. The patient lies supine with the legs fully extended and the hips moderately abducted. To test abduction, the patient actively pushes out against the examiner's resistance against the lateral malleoli. Adduction is tested by movement against resistance at the medial malleoli.

## Knee

The knee is a compound condylar joint with three articulations: the patellofemoral and the lateral and medial tibiofemoral condyles with their fibrocartilaginous menisci. The knee is stabilized by its articular capsule, the patellar ligament, medial and lateral collateral ligaments, and anterior and posterior cruciate ligaments. The collateral ligaments provide medial and lateral stability, whereas the cruciatus provide anteroposterior and rotatory stability. Normal knee motion is a combination of flexion or extension and rotation. With flexion, the tibia internally rotates, and with extension, it externally rotates on the femur. The surrounding synovial membrane is the largest of the body's joints; it extends 6 cm proximal to the joint as the suprapatellar pouch beneath the quadriceps femoris muscle. Several important bursae are found around the knee, including the superficial prepatellar bursa, the superficial and deep infrapatellar bursae, the pes anserine bursa distal to the medial tibial plateau, and the posterior medial semimembranous and posterolateral gastrocnemius bursae. Knee extension is primarily mediated by the quadriceps femoris muscle; knee flexion is mediated by the hamstrings. The biceps femoris muscle externally rotates the lower leg on the femur, whereas the popliteus and semitendinous muscles mediate internal rotation.

In taking the history of a patient with knee complaints, the examiner should ask the patient about symptoms of knee locking, catching, or giving way. *Locking* is the sudden loss of ability to extend the knee; it usually is painful and may be associated with an audible noise, such as a click or pop. It often implies extensive intra-articular abnormality, including loose bodies or cartilaginous tears. *Catching* refers to a subjective sensation of the patient that the knee might lock; the patient may experience a momentary interruption in the smooth range of motion of the joint but is able to continue with normal motion after this brief hesitation. Catching usually implies less abnormality than true locking and may occur in various pathologic conditions. True giveway indicates that the knee actually buckles and gives out in certain positions or with certain activities. It is important to elicit details of the patient history to verify this common subjective complaint. Patients often experience a sensation that the knee will give out when it actually does not. Other patients say their knees are "giving out" to describe severe pain that necessitates stopping an activity. True give-way implies severe intra-articular abnormality, such as an unstable joint from ligamentous injury or incompetence.

Examination of the knees should always include observation of the patient while standing and walking (see Chapter 48). Deviation of the knees, including genu varum (lateral deviation of the knee joint with medial deviation of the lower leg), genu valgum (medial deviation of the knee with lateral deviation of the lower leg), and genu recurvatum (hyperextension deformity of the knee), is most easily evaluated with the patient standing. The patient also should be observed ambulating for evidence of gait abnormalities.

Inspection should be done with the patient standing and supine. It is essential to compare side to side, noting any asymmetry that may be caused by swelling or muscle atrophy. Suprapatellar swelling with fullness of the distal anterior thigh that obliterates the normal depressed contours along the sides of the patella usually indicates knee joint effusion or synovitis. Localized swelling over the surface of the patella is generally secondary to prepatellar bursitis (Figure 40-9). Patellar alignment should be noted, including

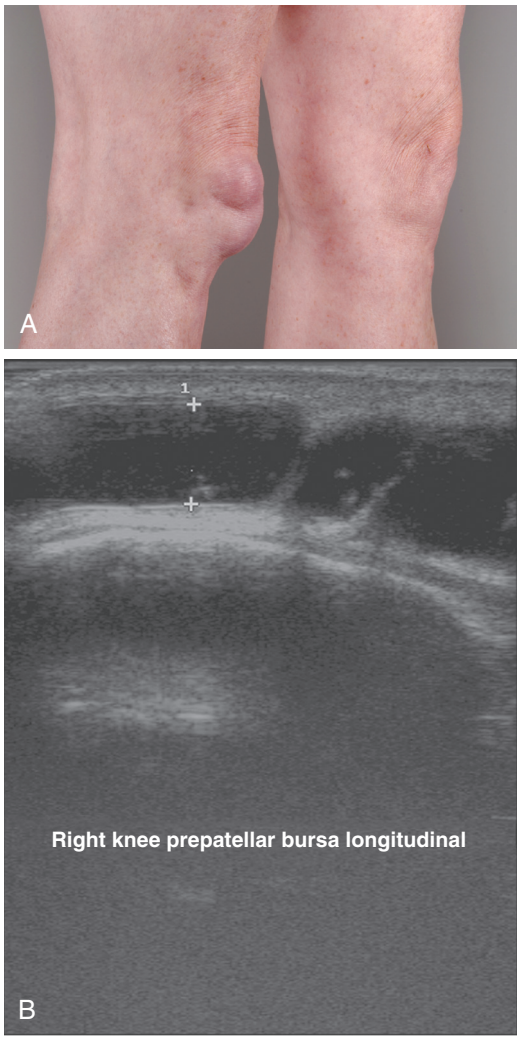

**Figure 40-9** Prepatellar bursitis. **A,** Note the cystic swelling overlying the right patella, with the appearance of two separate compartments of bursal swelling. **B,** High-resolution ultrasound image of the same patient showing collection of anechoic fluid with an internal septation.

high-riding or laterally displaced patellae. The examiner also should inspect the knee from behind to identify popliteal swelling caused by a popliteal or Baker cyst, most commonly caused by medial semimembranous bursal swelling. If the calves appear asymmetric, calf circumference should be measured and compared bilaterally. Popliteal cysts may rupture and dissect down into the calf muscles, resulting in enlargement and palpable fullness. Edema may be present if the cyst causes secondary venous or lymphatic obstruction. Acute rupture and dissection of a popliteal cyst can mimic thrombophlebitis, with local pain, heat, redness, and swelling. This is probably a more common cause of unilateral calf swelling in patients with RA than is deep venous thrombosis. The two conditions may be difficult to distinguish on physical examination alone.

Quadriceps femoris muscle atrophy usually develops in chronic arthritis of the knee. Atrophy of the vastus medialis muscle is the earliest change and may be appreciated by comparing the two thighs for medial asymmetry and circumference. Measurement of the thigh circumference should be performed at 15 cm above the knee to avoid spurious results due to suprapatellar effusions.

Palpation of the knee should be performed with the joint relaxed. This usually is best accomplished with the patient supine and the knees fully extended and not touching. Palpation should begin over the anterior thigh approximately 10 cm above the patella. To identify the superior margin of the suprapatellar pouch, which is an extension of the knee joint cavity, the examiner should palpate the anterior thigh, moving distally toward the knee. Swelling, thickening, nodules, loose bodies, tenderness, and warmth should be noted. A thickened synovial membrane has a boggy, doughy consistency, which differs from the surrounding soft tissue and muscle. It usually is palpated earlier over the medial aspect of the suprapatellar pouch and the medial tibiofemoral joint. To enhance detection of knee fluid, any fluid in the suprapatellar pouch is compressed with the palm of the hand placed just proximal to the patella. The synovial fluid forced into the inferior distal articular cavity is palpated with the opposite thumb and index finger laterally and medially to the patella. If the examiner alternates compression and release of the suprapatellar pouch, the synovial thickening can be differentiated from a synovial effusion. An effusion intermittently distends the joint capsule under the thumb and index finger of the opposite hand, whereas synovial thickening does not.
